straight line (extraction = 0.93 − 0.071 Ca_{O_2}, r = 0.993). Finally, over the physiologic range of fetal P_{O_2}, there is a linear relationship between P_{O_2} and oxygen saturation[11]; hence one would expect an inverse, linear relationship between extraction and Pa_{O_2}, as was found in the present study.

There are clear differences in the conditions under which the measurements of human fetal oxygen extraction were obtained compared with those under which the antenatal data were collected from sheep. However, analysis of the information obtained from sheep during labor and delivery resulted in a predicted fetal oxygen extraction similar to that calculated from the data collected from lambs in utero (25.8% and 27.3%, respectively, at P_{O_2} = 20 mm Hg). Hence the use of the regression analysis to predict human fetal oxygen extraction in utero from cord blood data obtained at delivery appears to be valid.

There do not appear to be any published studies on human fetal oxygen extraction, although some reports give data on umbilical venous and arterial oxygen saturation or content that can be used to calculate extraction. Ramanathan et al.[12] studied women undergoing elective cesarean section who were divided into four groups on the basis of the oxygen concentration administered, which ranged from 21% to 100%. From their data, a regression equation for the relationship between umbilical arterial P_{O_2} and fetal oxygen ex-

traction can be calculated. The regression coefficient (−2.64) and y-intercept value (100.1) were similar to values obtained in the present study. In addition, the calculated extractions at P_{O_2} = 20 mm Hg are similar in the two studies (47.5 versus 47.0).

Aside from the higher oxygen extraction noted in the human fetus, there were also a lower P_{O_2} and pH compared with those of fetal lambs in utero. These differences are likely due in part to the delivery process, inasmuch as similar changes were observed during labor in sheep. During vaginal delivery, fetal oxygen delivery could be impaired by reductions in uterine and umbilical blood flow during uterine contractions, whereas with cesarean section there could be impairment of maternal and fetal-placental blood flows by uterine manipulation or maternal aortic and caval compression, in turn leading to reductions in fetal oxygenation[13]. The umbilical venous-arterial difference in oxygen content is also higher in the human fetuses than in the fetal lambs in utero. Although this could be a consequence of a reduced umbilical blood flow during delivery, a venous-arterial oxygen difference of 6 to 7 vol/100 ml is also consistent with the reported values for umbilical blood flow (120 ml/min · kg)[2] and oxygen consumption (7.6 ml/min · kg)[4] in the human fetus.

Another finding in the present study is the wide variation in umbilical arterial and venous P_{O_2} with both vaginal delivery and cesarean section. In vaginal delivery, the variation may relate to differences in the duration or severity of labor. With cesarean section, it may be due more to variations in the uterine incision-to-delivery time interval, inasmuch as Datta et al.[13] reported a deterioration in fetal blood status during cesarean section when this interval was increased beyond 3 minutes. In any event, the variation in cord blood P_{O_2} makes it difficult to predict normal vascular oxygen tension in the human fetus in utero. This is an important requirement in the present study, because the conclusion that oxygen extraction is higher in the human fetus is based in part on the assumption that human fetal umbilical arterial P_{O_2} is similar to that observed in the fetal lamb (~20 mm Hg), yielding a value for extraction of ~47%. For extraction in the human to be 30%, Pa_{O_2} would have to be ~27 mm Hg. In physiologic terms, this means that for the human fetus to have a level of oxygen extraction comparable to that of the fetal lamb, umbilical venous P_{O_2} and oxygen saturation would have to be high enough to compensate for the lower rate of umbilical blood flow in the human and hence yield a value for oxygen delivery similar to that in the sheep fetus. To achieve this, umbilical venous blood would have to be nearly fully saturated with a P_{O_2} of 50 to 55 mm Hg. This is higher than the accepted normal range for the fetal lamb but is similar to values reported for the fetal foal and cow.[14] Recently, Nicolaides et al.[15] reported human umbilical venous blood gas values measured in samples obtained by percutaneous fetal blood sampling in second-trimester pregnancies. The mean P_{O_2} was ~55 mm Hg. It can be calculated from an assumed umbilical venous-arterial oxygen difference of 6 to 7 vol/ml that umbilical arterial P_{O_2} would be ~30 mm Hg, which compares favorably with the predicted value of 27 mm Hg in the present study.

If the high vascular P_{O_2} reported for the human fetus in the second trimester[15] is also present in the third trimester, the human fetus undergoes a much more profound deterioration in blood gas status during the delivery process than has been found for the fetal lamb in this and previous studies.[16] Moreover, it could also mean that oxygen delivery and extraction in the human fetus are similar to the levels observed in the fetal lamb. However, the results would be achieved in different ways in the two species. In the lamb, delivery is high largely because cardiac output and umbilical blood flow are high. In contrast, in the human, a comparable rate of oxygen delivery would be achieved in part by the higher hemoglobin concentration and in part by a higher umbilical venous P_{O_2} and oxygen saturation, with the latter differences suggesting a more efficient system for placental oxygen transfer than in the sheep. These differences, and others,[3] indicate significant quantitative differences in the systems for fetal oxygen delivery in the human and sheep.

Endometrial carcinoma occurring in patients under the age of 45 years

J. D. Jeffery, M.D., R. Taylor, M.D., D. I. Robertson, M.D., and G. C. E. Stuart, M.D.
Calgary, Alberta, Canada

Endometrial adenocarcinoma is frequently unsuspected in women under the age of 45 years by the gynecologist or the pathologist, but it does occur. Twenty-seven cases of endometrial adenocarcinoma in this age group, from 1980 to 1985, were reviewed clinically and pathologically. Five cases were excluded by histologic examination. Obesity and abnormal vaginal bleeding were shown to be risk factors. Endometrial screening is to be encouraged. This cancer may arise de novo rather than from a premalignant precursor. Implications of this neoplasm for the premenopausal woman are considered. (Am J Obstet Gynecol 1987;156:366-70.)

Key words: Carcinoma, endometrium, younger age group

Endometrial adenocarcinoma is classically a disease of the older, post-menopausal woman. Obesity, impaired carbohydrate metabolism, nulliparity, late onset of menopause, hypertension, anovulatory menstrual cycles, and exogenous estrogen administration have been documented as risk factors for the development of this neoplasm in the population at risk. These same risk factors may not apply to a younger population, yet 2% to 3% of cases of endometrial adenocarcinoma occur in women under the age of 45 years.[1] Gallup and Stock[2] identified 14.4% of their cases to have been diagnosed at age 40 years or less. Endometrial cancer is frequently unsuspected clinically or pathologically in women under the age of 45 years. This tumor does exist and may arise de novo in some cases in the presence of otherwise normal-appearing, functioning endometrium. The presence of obesity and abnormal vaginal bleeding should encourage a greater practice of endometrial sampling. The purpose of this retrospective, clinicopathologic study is to evaluate the risk factors in patients among this premenopausal subgroup and to describe their disease histologically.

Material and methods

Twenty-seven patients diagnosed from 1980 to 1985 as having endometrial adenocarcinoma were accessioned through the Cancer Registry at the Tom Baker Cancer Centre, Calgary, Alberta, Canada. Women under the age of 45 years were selected to obtain a premenopausal study group for comparison with current literature. Clinical data were obtained by chart review of the time of diagnosis and by correspondence, as necessary, with the primary care physicians. Ideal body weight was assumed to be 100 pounds for a height of 60 inches, with an allowed increase of 5 pounds for each inch over a height of 60 inches. Two of the authors (R. T., D. I. R.) reviewed the original histologic material of all patients, as well as recuts on selected blocks of tissue as necessary. Statistical analysis was done by the χ^2 method.

Results

Five patients were excluded after histologic review, with an error in coding for uterine malignancy other than endometrial adenocarcinoma or a disagreement with the histologic diagnosis of endometrial adenocarcinoma. The remaining 22 patients under the age of 45 years represent 5% of cases of endometrial adenocarcinoma documented in Southern Alberta from 1980 through 1985. The mean age of these 22 patients was 39.0 years (range 26.6 to 44.9 years, see Fig. 1). The mean age of menarche, identified in nine patients, was 12.8 years (range 9 to 15 years); nine patients were nulligravid, and 13 (59%) were parous.

Eleven patients (50%) were more than 20% above their ideal body weight (Fig. 2). Eight (36.4%) of the twenty-two women were smokers. The mean arterial blood pressure of all patients was 91.4 ± 12.7 mm Hg. Before diagnosis, only two patients were receiving antihypertensive medications; only one patient had been recognized as having diabetes mellitus, type II. Two patients had exposure to clomiphene citrate as an ovulation induction agent, within 12 months before diagnosis of disease. It was not possible from chart review to draw any meaningful conclusions regarding incidence of oral contraceptive pill use among the study patients. One of the 22 study patients had a bilateral salpingo-oophorectomy performed 10 years before diagnosis, because of bilateral mucinous cystadenomas, but this patient had been maintained on a regimen of cyclic conjugated estrogens during the interval.

The most common physical findings documented by the assessment of the admitting physician at the time of diagnosis were clinically increased uterine size (nine of 22 patients) (40.9%) and obesity (eight of 22 patients) (36.4%). All patients but one had a reported abnormality of the usual menstrual pattern (see Table I). Heavy or irregular menses was defined as an increase or change by more than 2 days from the regular menstrual pattern.

Five patients (22.7%) failed to have carcinoma diagnosed before hysterectomy. The remaining 17 patients each had carcinoma diagnosed on prehysterectomy uterine curettings. One patient has been lost to follow-up after the diagnosis was made by fractional curettage. Surigcal management is as listed in Table II. Surgical therapy was performed at various referring institutions before review at the Cancer Centre. Three patients have received postoperative external beam pelvic radiation, followed by vaginal vault radiation. Two of these cases were for histologic evidence of endocervical involvement and the third patient had Stage IB, grade 1 disease with full-thickness myometrial invasion. One patient has received chemotherapy in the form of Adriamycin, cyclophosphamide, and progestogens. She represents the only patient to die in the present series and had an associated second primary

malignancy of Stage III endometrioid adenocarcinoma of the ovary. A fourth patient has received external beam pelvic radiation followed by administration of Alkeran, tamoxifen, and dexamethasone as postoperative adjuvant therapy for clinical Stage IB–surgical Stage IV disease. All adjunctive therapy was given at the Cancer Centre. All patients but one are alive and well without evidence of recurrence, with a range of follow-up from 6 to 73 months (average = 32.4 months).

On clinical and pathologic review, the tumors were staged and graded according to criteria of the International Federation of Gynecologists and Obstetricians (Table III). The mean age at presentation for patients with grade 1 tumors was 39.0 years compared with 39.4 years for grade 2 tumors; the mean age at presentation for clinical Stage 1 disease was 38.5 years and for Stage 2 disease it was 42.8 years. Four patients had coincidentally associated gynecologic pathology, as defined in Table IV. The nonmalignant endometrium within the specimen of each case was examined histologically for evidence of precursor lesions to endometrial adenocarcinoma; these results are shown in Table V.

The association between age, smoking history, mean arterial blood pressure, and deviation from ideal body weight was compared with clinical stage and grading of the tumor and precursor endometrial lesions. None of these associations were clinically significant by χ^2 analysis. Nine of 14 cases (63.6%) with an endometrial background of atypical adenomatous hyperplasia occurred in women older than 40 years. This was approaching clinical significance ($p = 0.12$), but there was no established correlation between a precursor lesion and clinical stage or grading. Menstrual bleeding pattern had no correlation with clinical stage or grading, but the presence of atypical adenomatous hyperplasia of the endometrium was strongly associated with heavy, irregular menses ($p = 0.0046$).

Comment

Endometrial adenocarcinoma in young, premenopausal women accounted for 5% of cases in Southern Alberta. This is higher than classically quoted figures but not as high as those of other recent publications.[1-3] This report and others support a trend for increasing incidence with advancing age; the present cohort of patients representing only 5% of reported cases may be attributed to a relatively young and mobile population in Southern Alberta.

An associated diagnosis of the polycystic ovary syndrome may be found in up to 20% to 30% of cases of endometrial adenocarcinoma in young, premenopausal women.[1, 2] In only one of the present 22 cases was there histologic evidence of anovulation. Patient obesity and nulliparity seem to be strongly associated with the development of this cancer in young women[4-8]; this theory is supported in the present review by the finding

that half of the patients were more than 20% heavier than ideal body weight. There are at least two studies, however, to challenge these associations.[3, 8]

The effect of tobacco, if any, is not clear. Some authors[9] claim no association with increased risk of developing endometrial adenocarcinoma, while others maintain smoking will increase the risk in premenopausal women and decrease the risk in postmenopausal women.[10] Exogenous estrogens have been claimed to promote this malignancy, and this may include sequential oral contraceptive pills.[5] The combination oral contraceptive pill has not been implicated directly in this promoter role.[11, 12]

In this study, 21 of 22 patients presented to their primary care physicians with abnormal vaginal bleeding. The most common physical abnormalities were increased uterine size and/or patient obesity. These combinations of signs and symptoms should alert the physician to the possibility of underlying endometrial abnormality, yet the diagnosis of adenocarcinoma was first made after hysterectomy in 22.7% of cases. Although screening the general population with routine endometrial sampling is not cost effective, it should be used more frequently in this selected group of women.[8, 13] As a screening procedure, premalignant pathologic conditions (for instance, endometrial hyperplasia) must be followed with formal cervical dilatation and fractional curettage of the endocervical canal and endometrial cavity.

There was a trend in the study population for atypical adenomatous hyperplasia of the endometrium to occur in women over the age of 40 years, but there was no statistically significant association between "precursor" lesions and adenocarcinoma. Likewise, no statistically significant correlation was found when menstrual pattern, smoking history, age, mean arterial blood pressure, or deviation from ideal body weight was compared with histologic grade or clinical stage of the tumor or precursor endometrial histologic features.

The lack of precursor pathologic conditions (adenomatous hyperplasia) in seven of the 22 patients suggests the possibility that some cases of endometrial adenocarcinoma may arise de novo. The appearance of normally functioning background endometrium, as seen in 15 of the present cases, should not deter the pathologist from diagnosing endometrial adenocarcinoma. As well, it challenges the role of continuous unopposed estrogen in the pathogenesis of this malignancy.

Other investigators[14, 15] have proposed two variants of carcinoma. One variety seems to be estrogen-dependent and is associated with adenomatous hyperplasia, better histologic differentiation-grading, less myometrial invasion, and a better prognosis. The other variety is hormone-independent and carries a worse prognosis. The findings from this present study do not allow identification of such a dichotomous disease process.

Four of the 21 patients available for follow-up in this study did not have surgical castration. Three of these patients had Stage IB, grade 1 tumors and one patient had Stage II, grade 1 disease. These four have been followed up for 6 to 73 months and all remain alive and clinically free of disease to this point. Although bilateral oophorectomy is to be recommended as part of the initial surgical procedure, surgical reexploration, in order to remove the ovaries after hysterectomy alone, is likely unnecessary in patients with early stage disease. A recent article states that endometrial adenocarcinoma does not appear to be a contraindication to estrogen replacement therapy in patients with Stage I disease. Cyclic estrogen plus progestogens may even provide a protective effect.[17] Although specific suggestions regarding the role of ovarian conservation cannot be made from the present study, the routine procedure of bilateral salpingo-oophorectomy is open to question in young women with low-grade, low-stage disease.

Endometrial adenocarcinoma is frequently unsuspected clinically or pathologically in women under the age of 45 years. One may conclude that a greater practice of endometrial sampling is to be encouraged, especially in obese women with abnormal vaginal bleeding and/or an enlarged uterus. The tumor may arise de novo, in some cases in the presence of normal-appearing and functioning endometrium. The pathologist should not be deterred from reporting a diagnosis of endometrial adenocarcinoma in the absence of an identified transition from endometrial hyperplasia to invasive cancer. Although the tumor is usually of low grade and low stage, it may be aggressive and require adjuvant therapy. The implications of long-term estrogen deprivation after hysterectomy and bilateral salpingo-oophorectomy in young patients must be cautiously considered against the unknown risk of ovarian conservation or postoperative estrogen replacement therapy.

Uterine sarcoma: An analysis of 74 cases

Allan L. Covens, M.D., Jeffrey A. Nisker, M.D., William B. Chapman, M.D., and H. Hugh Allen, M.D.

London, Ontario, Canada

In order to determine whether recent methods of diagnosis and treatment have resulted in an improved survival for patients with uterine sarcoma, we reviewed 99 cases treated in our center from 1970-1985. Morphologic characteristics of 74 tumors were specifically reassessed for this study. All tumors were graded. Of 42 Stage I cases that were morphologically assessed, tumor-positive pelvic lymph nodes were found in two of the 15 patients in whom sampling was done. No cases of tumor-positive para-aortic nodes were found in 14 patients with Stage I disease. In Stage I and Stage II, no cases of positive para-aortic nodes were found in association with negative pelvic nodes. The 2- and 5-year survival rates in Stage I were 47.4% and 29.4%, respectively. Local recurrence decreased ($p < 0.01$) in Stage I from nine of 22 cases in which operation alone was performed to none of 15 cases in which pelvic radiotherapy was added, but no improvement in the 5-year survival rate was observed. As with lymphadenectomy and radiotherapy, the recent use of chemotherapy for uterine sarcoma had no impact on survival. (Am J Obstet Gynecol 1987;156:370-4.)

Key words: Uterine sarcoma, diagnosis, treatment, survival

Sarcomas of the uterus account for 3% to 5% of uterine malignancies.[1-4] This infrequent occurrence, as well as the multiple morphologic features, has made study and recommendations for treatment difficult. In recent years lymphadenectomy, adjuvant radiotherapy, and chemotherapy have been suggested as possible therapeutic modalities that might improve the generally poor prognosis. We thus evaluated these methods for the treatment of uterine sarcoma in a large regional cancer center.

rence were retrieved. Information not present in the initial chart review was added from referring physician records, other cancer treatment center's records, individual hospital charts, and personal telephone calls to the patients. Follow-up was 100%.

Clinical stage was based on guidelines of the International Federation of Gynecologists and Obstetricians for uterine neoplasms. Pathologic material was reviewed specifically for this study by one of the authors (W. B. C.) using the classification of Hendrickson and Kempson.[5] Low-grade endometrial stromal sarcomas (endolymphatic stromal myosis) were included. The criteria for diagnosis of leiomyosarcoma were >10 mitotic figures per 10 high-power fields or five to 10 mitotic figures per 10 high-power fields with moderate or severe atypia. An average of 11 blocks of primary tumor had been prepared per case, and the range was seven to 21. At least one slide stained with hematoxylin and eosin was reviewed for each block, and in some cases special stains were also available for review. A mitotic count was done for all cases; this was reported as the number of mitotic figures per 10 high-power fields, with the use of a 40× objective and 10× ocular. At least 10 high-power fields in the most cellular part of the tumor were examined in each case. Atypia was graded as mild, moderate, or severe.

Groups were compared with the use of χ^2 analysis and means were compared with Student's t test. The 2- and 5-year survival rates were reported as crude survivals.

*Three patients underwent curettage only.

Results

Of the 99 cases initially diagnosed as uterine sarcoma, 25 were excluded before pathologic review because of unavailability of slides. All of the original diagnoses for the remaining 74 cases were confirmed. As shown in Table I, malignant mixed müllerian tumors accounted for 58.1% of all tumors. The tumor grading is also presented in Table I.

The mean age of the patients was 61.9 years, and the ages ranged from 15 to 92 years. The mean ± SD ages by histologic types were: malignant mixed müllerian tumor, 65.8 ± 13.0 years; endometrial stromal sarcoma, 55.1 ± 17.4 years; leiomyosarcoma, 55.2 ± 11.5

		2 yr	*5 yr*
I	42	47.4	29.4
Malignant mixed müllerian tumor	23	31.6	23.5
Endometrial stromal sarcoma	5	80.0	75.0
Leiomyosarcoma	11	72.7	33.3
Others	3	0	0
II	9	25.0	12.5
III	10	20.0	0
IV	13	9.1	0

years; others, 60.6 ± 13.1 years. The mean age of patients with leiomyosarcoma was significantly younger than that of patients with malignant mixed müllerian tumors ($p < 0.01$). The most common presenting complaints were abnormal vaginal bleeding (79.7%), pelvic or abdominal pain (16.2%), an enlarged uterus (12.2%), vaginal discharge (9.5%), and abdominal or pelvic mass (9.5%).

The clinical and surgical staging is described in Table II. At the time of operation, 23.2% of patients with clinical Stage I disease were noted to have more advanced disease.

Pelvic lymph node metastases were found in two of 15 Stage I cases, but no para-aortic nodal metastases were found in 14 patients (Table III). There were no cases of positive para-aortic nodes with negative pelvic nodes (n = 13). In Stage II, tumor-positive nodes were found in all four cases where pelvic nodes were removed and in both cases where para-aortic lymphadenectomy was performed. In Stages I and II malignant mixed müllerian tumors accounted for 83.3% of cases with tumor-positive lymph nodes. In both Stage I and Stage II there were no 2-year survivors in any of the patients with tumor-positive pelvic or para-aortic lymph nodes. In Stage I, the 5-year survival rate for patients with negative nodes (25.0%) was not significantly different from that in those cases where the lymph nodes were not sampled (34.8%).

The 2- and 5-year survival rates by stage are shown in Table IV. The overall crude 2- and 5-year survivals were 33.8% and 17.5%, respectively, and 47.4% and 29.4%, respectively, for Stage I. Fifty-one patients have died, with all deaths occurring within 5 years of initial operation.

Survival rates in Stage I for the various treatment regimens are described in Table V. Although there was a significant decrease ($p < 0.01$) in local recurrence with the addition of radiation to operation (none of 15) compared with that in operation alone (nine of 22), the 2- and 5-year survivals were similar. When simple hysterectomy is compared with radical hysterectomy in patients with Stage I disease (having no additional therapy), the 2- and 5-year survivals were not significantly different (Table V).

Twenty-four patients received chemotherapy. The various regimens included: vincristine, actinomycin D, and cyclophosphamide (eight patients); cyclophosphamide, vincristine, Adriamycin, and dimethyl-triazeno imidazole carboxamide (seven patients); and cisplatin-based therapies (five patients). Adriamycin, in addition to other chemotherapeutic agents, was given to 15 patients. No patient received single-agent chemotherapy. No change in survival was observed with the addition of chemotherapy.

There have been tumor recurrences in 35 patients and second recurrences in 11. Recurrences were observed within 9 months in 54.3% of cases, and all recurrences observed were within 4 years of initial diagnosis. As noted in Table VI, 51.4% of first recurrences involved the pelvis, with 45.7% involving the pelvis only. The second most common site of initial recurrence was the lung (31.4%), with 22.9% being pulmonary only. The abdomen was involved in 20.0% in recurrences.

Survival according to histologic type is given in Table I. When the various morphologic types are compared (Table I), no significant differences in survival were noted, with the exclusion of low-grade endometrial stromal sarcoma. All malignant mixed müllerian tumors showed areas of severe atypia and high mitotic counts in both the sarcomatous and carcinomatous areas. The same was true for the sarcomatous portions

Table V. Stage I: Primary therapy and survival

	Simple hysterectomy	*Radical hysterectomy*	*Operation plus radiation*	*Radiation plus chemotherapy*	*Operation plus radiation plus chemotherapy*
n	17	5	15	4	1
Survival (%)					
2 yr	43.8	50.0	46.2	75.0	0
5 yr	25.0	33.3	41.7	50.0	0

of the unclassified sarcomas, the mixed sarcoma, and the adenosarcoma. Leiomyosarcoma was analyzed both by degee of atypia and by mitotic count. Thirteen cases of leiomyosarcoma had >10 mitoses per 10 high-power fields and four cases had five to nine mitoses per 10 high-power fields with moderate to severe atypia. There was a better 5-year survival with lower mitotic counts and less atypia, but the small numbers preclude significance testing.

Four patients had previous pelvic radiation, with the average time from radiation to diagnosis being 16 years, (range 5 to 27 years). The indications for the previous radiation included: cervical carcinoma (n = 2), bladder carcinoma (n = 1), and ovarian carcinoma (n = 1). Morphologically, three were malignant mixed müllerian tumors and the other was an adenosarcoma.

Comment

The 2- and 5-year survivals for Stage I reported in this paper are comparable with those of previous studies[3] but less than those of others.[1, 6-8] The single most important predictor of survival is stage. In this study, grade appears to be of use prognostically for endometrial stromal sarcoma and possibly leiomyosarcoma. The usefulness of grading in endometrial stromal sarcoma is widely accepted[9-11] and a correlation between grade and prognosis has been shown for leiomyosarcoma.[12] Conversely, grading of malignant mixed müllerian tumor does not offer any prognostic value,[12, 13] a conclusion with which we agree.

In this study, as in other studies addressing lymphadenectomy for uterine sarcoma,[6, 14] small numbers preclude meaningful conclusions. The fact that five of six patients with positive nodes had morphologic features of malignant mixed müllerian tumor agrees with a previous study[6] stating that malignant mixed müllerian tumors have the most propensity to spread via the lymphatics. As no patient with tumor-positive lymph nodes survived 2 years, lymphadenectomy appears to be of limited usefulness.

The incidence of sarcoma in patients with a history of previous pelvic radiation is comparable to that of previous reports.[1, 2, 15] Rarely is radiation used for benign disease today, but the numerous indications in the past may be one cause of the higher incidence reported in previous studies.[6, 16] The higher proportion of malignant mixed müllerian tumors observed in this study is consistent with that of previous reports.[2, 15]

The inaccuracies of clinical staging are evident in the fact that 23.2% of Stage I cases were understaged when intraoperative findings were evaluated. The high proportion of distant recurrences (28.6%) in Stage I disease further emphasizes the need for systemic therapy as part of the primary treatment plan. The propensity for pulmonary recurrences (31.4% overall and 22.9% as an isolated location) further emphasizes the need for adjuvant chemotherapy. The aggressiveness of uterine sarcomas is further reflected by the fact that more than 50% of recurrences developed within 9 months of initial treatment. Low-grade endometrial stromal sarcoma, however, behaves differently from other uterine sarcomas in its tendency to recur after many years. Comparisons of primary treatment modalities could be addressed only in Stage I and II disease in this study. As in previous reports,[1-3, 7, 8] the addition of radiotherapy did not significantly improve survival. Despite the adjuvant use of chemotherapy in 14.9% of our patients, neither survival rate nor recurrence interval was improved.

The correlation of negative pelvic lymph nodes with negative para-aortic nodes questions the value of paraaortic lymphadenectomy. Similarly the fact that there were no survivors with tumor-positive pelvic lymph nodes demonstrates the futility of therapeutic lymphadenectomy in uterine sarcoma. Radical hysterectomy has not been found to improve survival in Stage I disease and therefore has no role in uterine sarcoma ex-

cept possibly for endometrial stromal sarcoma with potential parametrial involvement.

The addition in recent years of radiotherapy, lymphadenectomy, and chemotherapy to hysterectomy for uterine sarcoma has not impacted on the poor prognosis. More effective chemotherapeutic agents would seem the most appropriate direction for future studies of uterine sarcoma.

Laser surgery for vulvar intraepithelial neoplasia: Principles and results

V. C. Wright, M.D., and Eleanor Davies, M.D.
London, Ontario, Canada

Twenty-nine patients with grade 3 vulvar intraepithelial neoplasia were treated with the carbon dioxide laser while they were under anesthesia. Superficial lesions in nonhairy areas were vaporized to <1 mm, but lesions extending onto hairy areas were vaporized to 3 mm to destroy disease in skin appendages. Eighty-three percent of lesions involved nonhairy areas alone. Seventy-two percent of cases were cured by one laser application, 25% by two, and one case by three. Two patients had permanent hair loss after healing. The laser is an appropriate modality for lesions in nonhairy areas but scalpel excision is probably better for vulvar intraepithelial neoplasia in hairy areas. (AM J OBSTET GYNECOL 1987;156:374-8.)

Key words: Laser surgery, vulvar intraepithelial neoplasia, vulvar carcinoma in situ

Vulvar intraepithelial neoplasia has been considered a rare disease of early menopausal and postmenopausal women. Today, however, it is being seen more commonly in young, reproductive-aged women. Many of the women having a diagnosis of vulvar intraepithelial neoplasia have a history of vulvar viral infections, particularly human papillomavirus.[1] This fact and other evidence has led investigators to suspect a cause-and-effect relationship.[2-5] Vulvar intraepithelial neoplasia can be found anywhere on the vulva. Most lesions occupy nonhairy areas, but they can also occur in hairy areas.[6] As many as 50% of cases are multifocal areas,[6] and lesions can extend from one area onto another,

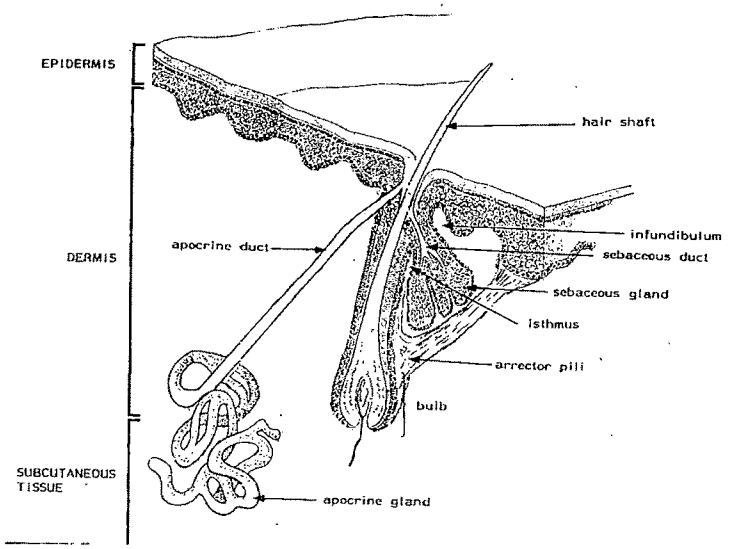

Fig. 2. Histologic structural relationship of the sebaceous gland, hair follicle, and sweat gland.

such as from the vulva to the perianal skin (17% of cases) or clitoral prepuce (18% of cases).[1]

Treatments by simple excision, simple vulvectomy, skinning vulvectomy, cryosurgery, and topical 5-fluorouracil have been disappointing.[1, 6-8] Recurrence is the same, about 30%, after local incision and simple vulvectomy, and in 39% of cases recurrence is found at the margin after skinning vulvectomy.[9] As many as 48% of cases of multifocal disease recur.[10] Topical 5-fluorouracil is frequently too irritating for patients to continue the 4- to 6-week regimen.[6, 9] Cryosurgery simply does not work[1] and repeated surgical procedures often produce unsatisfactory cosmetic results.

The apparently rising incidence of vulvar intraepithelial neoplasia in younger, sexually active women and the need for re-treatment in many patients have motivated some surgeons to use the carbon dioxide laser as a surgical modality for this disease. This has met with varying success, ranging from acceptable[11] (73% disease free after one to three laser applications) to dismal[12] (74% of one series of patients had three to six laser applications and almost 10% of the women still had disease), and complications of bleeding and infection have been reported.[11, 13, 14] The purpose of this paper is to illustrate that satisfactory cure rates, few complications, and excellent cosmetic results can be obtained for both unifocal and multifocal grade 3 vulvar intraepithelial neoplasia disease with the carbon dioxide laser. The operative approaches are based on the histologic depths of disease in different areas of the vulva and the potential for vulvar intraepithelial neoplasia to involve underlying adnexal structures.

Table I. Postoperative care after vulvar laser surgery

1.	Tea sitz baths or warm tea bag compresses four times a day
2.	Tannic acid ointment (composed of 5% tannic acid and 95% PCCA concentrate* or 5% tannic acid and 95% petrolatum supplied in 50 to 100 gm container) applied to the wound three times a day
3.	One quarter strength hydrogen peroxide sitz baths as needed (one part hydrogen peroxide and four parts water), should a cleansing agent be necessary
4.	Use of a hair dryer to dry the skin after bathing and sitz baths
5.	Silver sulfadiazine applied topically as necessary to control superficial bacterial infection
6.	Analgesics as necessary
7.	Avoidance of constricting clothing
8.	No intercourse until the area is healed

Structure of the skin

To eliminate vulvar intraepithelial neoplasia it is necessary to understand the structure of the skin and its underlying appendages and recognize which ones are likely to be become involved by disease and to what depth (Figs. 1 and 2). The structures in question are the external hair root sheath, the sebaceous gland and its duct, and the apocrine and eccrine glands and ducts. The external hair root sheath is a downward continuation of the epidermis. To the isthmus, including the entrance of the sebaceous duct, the squamous epithelium is stratified and produces keratin in the same manner as the vulvar skin surface. Below this level the sheath is not stratified and does not produce keratin. Because the upper parts of the hair root sheath and the lining of the sebaceous gland duct are contiguous with the surface epithelium and are composed of similar cells, these areas are susceptible to extension of disease.[15] Involvement of hair root sheaths to depths of 0.8 to 2.5 mm has been documented.[16] Involvement of the sebaceous duct, which is secondary to that of the sheath, occurs, although less often. The ducts of the eccrine and apocrine glands are lined by their own independent epithelium, which is not contiguous with the surface epithelium. Because of this these structures are far less likely to be involved. In the rare instance when disease has appeared to involve these ducts it has been to depths of ≤0.5 mm (Ferenczy A., personal communication, 1985).

Rationale for laser surgery

The reasons for using the carbon dioxide laser are many. This procedure requires microscopic scrutiny of disease because it is performed through an operating microscope. Normal tissue is left undisturbed and inflammatory response is reduced. The procedure usually does not produce bleeding and can be done on an outpatient basis with small lesions. Re-treatment can be performed, if needed, and exceptional cosmetic and functional results can be achieved. However, the latter advantage does not apply to all locations of vulvar intraepithelial neoplasia.

Because different areas of the vulva have different adnexal structures (hair follicles, sebaceous glands, apocrine and exocrine glands), the depth of disease and the technique of removing it with the carbon dioxide laser must vary. In some areas the carbon dioxide laser may not be the most appropriate surgical modality. For best management, the vulva, perineum, and anus should be divided into hairy and nonhairy areas.

Nonhairy areas. The nonhairy sites include the clitoris, labia minora, and inner surface of the labia majora, posterior fourchette, and anus. Since hair shafts are absent in these areas, it is unlikely that vulvar intraepithelial neoplasia will extend beyond the thickness of the epidermis (≤500 to 600 μm). Therefore, laser vaporization should be superficial and include the thickness of the epidermis only. This results in a histologic depth of <1 mm. Some heat conduction will extend the injury into the underlying superficial dermis. This may result in characteristic edema, blister formation, and pain. Such an injury may require 21 to 28 days to heal, but scarring should not occur with epithelial vaporization only.

Hairy areas. These areas are the outer surface of the labia majora and more lateral perineal and perianal areas. In these areas vulvar intraepithelial neoplasia can extend down the hair shaft (external hair sheath) and its associated sebaceous gland duct into the dermis as much as 2.5 mm. To eradicate disease in hairy areas, therefore, vaporization into the dermis of 3 mm is required to account for potential extension of the vulvar intraepithelial neoplasia along the hair shaft and its associated adnexal structure (duct of sebaceous gland). The amount of dermis lost depends on the site and extent of vulvar intraepithelial neoplasia involvement. This full-thickness vaporization results in destruction of the epidermis, dermis, and some complete epidermal structures.

Methods and material

During 1981 to 1985, 29 patients were referred to the Woman's Clinic at St. Joseph's Hospital in London, Ontario, Canada, for management of grade 3 vulvar intraepithelial neoplasia (severe dysplasia and carcinoma in situ). The majority of these patients had previous biopsies, either by the Keyes punch, by punch biopsy, or by incomplete local scalpel excision. A thorough colposcopic examination of the cervix, vagina, vulva, perineum, and anal area was carried out at the clinic. The appropriate areas were stained with acetic

Table II. Distribution of disease

acid. Toluidine was not used because we believe that acetic acid with magnification is more reliable. Frequently further biopsies were necessary to be sure that no invasive disease was present. A complete mapping of the disease was recorded.

All patients were under general anesthesia while they were treated. A surgical laser coupled to an operating microscope was used to produce an effective beam diameter of 2 mm with power density ranging from 650 to 1200 W/cm^2. Lesions were first outlined incorporating a colposcopically normal peripheral margin of 2 to 3 mm. Vaporization was carried out to a depth of just less than 1 mm in nonhairy areas and to 3 mm in hairy areas to ensure all disease was eradicated. Carbonized debris was then removed by irrigation or with a wet sponge. The vaporized defects were left to granulate and epithelialize.

Patients were given specific instructions for postoperative care. These are outlined in Table I. They were cautioned that infection and temperature elevation were possible and that they should call the office if either occurred. They were instructed to gently separate opposing lasered labia at least once each day during a sitz bath to prevent coaptation. They were informed that satisfactory healing might take 4 to 6 weeks after superficial vaporization and as long as 2 months after vaporization into the dermis. Patients were advised to avoid intercourse until satisfactory healing had taken place. Finally, they were warned that loss of pigmentation and alopecia might occur in areas of deep vaporization.

The initial postoperative evaluation was scheduled for 4 weeks after operation, the next at 3 months, and the third at 6 months. If a 6-month assessment revealed normal colposcopic findings, the patient was instructed to contact her referring physician for yearly examinations. A progress note was then sent to the clinic by the examining physician.

Results

In 83% of cases the grade 3 vulvar intraepithelial neoplasia lesions involved nonhairy areas only. In 17% lesions involved hairy and nonhairy areas. No lesions involved hairy areas alone (Table II). The most common single site was the posterior fourchette (52% of cases). The clitoris was involved in 6.9%. The majority of lesions occupied the posterior two thirds of the vulva. One patient had perianal extension of the disease.

Fourteen of 29 patients (48.3%) had a history of condyloma of the vulva. Four (13.8%) had condyloma associated with vulvar intraepithelial neoplasia at the time of treatment. Seven patients (24.1%) had a history of cervical intraepithelial neoplasia: grade 2 in three cases and grade 3 in four. No patient had a history of vaginal intraepithelial neoplasia. Twenty-seven of the 29 patients (93.1%) smoked.

Tea sitz baths and topical 5% tannic acid combined with 95% petrolatum were very effective in controlling pain. Laser surgery produced considerable pain and edema on the labia minora and three patients required a Foley catheter for as long as 10 days.

Two patients with vulvar intraepithelial neoplasia extending onto hairy areas healed with loss of hair. All other patients had satisfactory cosmetic results. No patient developed a systemic infection.

The success of laser surgery by site is shown in Table III. Most cases (72.4%) were cured by one laser procedure. One quarter of the cases required two laser procedures and one case required three treatments. In all cases the original lesions were eradicated. Seventy-five percent of lesions in nonhairy areas alone were cured by one laser application whereas only 60% of lesions that extended onto hairy areas were cured by one laser procedure.

At this writing two of the 29 patients (6.9%) who had normal findings 1 year after operation developed new disease. One had two laser procedures for a lesion in the posterior two thirds and she developed a new lesion in the upper third of one side of the vulva. This lesion was excised with a scalpel by another gynecologist two years after the laser procedure. One year later this same patient developed another lesion on the opposite side of the vulva in the upper third. She is presently contemplating having this area removed by laser. Another patient with a lesion in the posterior two thirds developed a new lesion adjacent to the site of laser treatment 3 years later. This was successfully removed by laser vaporization.

Comment

Baggish and Dorsey,[12] in an early investigation of laser surgery for vulvar intraepithelial neoplasia, recommended a uniform depth of vaporization of 3 mm for all areas of the vulva. However, because the labia minora and clitoris can be thinner than 3 mm, they might be destroyed by such depths of destruction. Furthermore, vaporization to that depth is unnecessary as well as hazardous in some areas, since adnexal structures that might be involved are absent in the nonhairy areas of the vulva where most lesions arise. In these nonhairy areas superficial ablation of the epithelium will be sufficient to eliminate the disease quickly, easily, and effectively, usually with one treatment. This has been noted by others.[14] The beam's slight thermal effect on adjacent and underlying normal tissue is enough to seal small blood vessels and lymphatics without interfering with healing. This enables the procedure to be performed without bleeding, prevents infection, and allows the vulva to heal without scarring.

Hairy areas, however, can be involved into the papillary and possibly the reticular dermis. Elimination of disease requires deep vaporization, which can cause delayed healing, scarring, and alopecia. We therefore advocate excising lesions in the hairy areas by scalpel. This approach to operation for grade 3 vulvar intraepithelial neoplasia, on the basis of the histologic depth of disease, is a reasonable alternative to more radical surgical procedures and seems a logical way of eliminating lesions while minimizing complications. This concept of histologic depth is consistent with the vaporization planes recently described by Reid[17] and warrants further investigation.

A CONTINUING AMA CATEGORY I MEDICAL EDUCATION PROGRAM

Postgraduate Obstetrics and Gynecology is a biweekly publication consisting of 26 lessons per year. Every two weeks during the calendar year each subscriber receives a state-of-the-art program which contains an original article focusing on a basic facet or contemporary problem and a self-test. Each article is prepared by an authority from among our distinguished editorial board or by a guest author selected by our editors. The articles are timely, authoritative, concise, and supplemented by visuals to provide clear illustrations of important details.

Each program concludes with a series of multiple choice questions which crystallize the most significant points of the article. The correct responses for each lesson are contained in the subsequent issue.

Accreditation—As an organization for continuing medical education, the University of Pennsylvania School of Medicine designates this continuing medical education activity as meeting the criteria for 1 credit hour per biweekly issue in Category 1 for Education Materials for the Physician's Recognition Award of the American Medical Association provided it has been completed according to instructions. This course has also been approved by the Americal College of Obstetricians and Gynecologists for 1 cognate per biweekly issue formal learning, as well as by the Committee on Continuing Education of the American Osteopathic Association for 1 credit hour per biweekly issue in Category 2B.

Each paid subscription is entitled to 26 CME credits and written CME certification is available upon request.

Please enter my subscription for one year (26 issues) of **Postgraduate Obstetrics & Gynecology.** I understand that my subscription will start with the issue following receipt of my payment ($160.00).

½ year subscription available—$90 for 13 issues.

(*Overseas orders* please add $35.00 for Air Mail orders.)

gainst the *B. fragilis* group?

94%
Mefoxin
active against 94% of isolates

the facts *still* favor Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

The *Bacteroides fragilis* group includes *B. fragilis, B. distasonis, B. ovatus, B. thetaiotaomicron, B. vulgatus.*

The percentages displayed are a weighted average of the susceptibilities reported for these organisms at an MIC breakpoint of 16 mcg/mL by the Antibiotic MIC Susceptibility Reports, National Summary, in *The Bacteriologic Report: Volume I 1986,* Totowa, NJ, BAC-DATA® Medical Information Systems, Inc. This average was weighted by the frequency of isolation of each organism.

NOTE: *In vitro* activity does not necessarily imply *in vivo* effectiveness.

MEFOXIN is contraindicated in patients who have shown hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

MEFOXIN is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Streptococcus faecalis*) and many strains of *Enterobacter cloacae.* Methicillin-resistant staphylococci are almost uniformly resistant to MEFOXIN.

For a Brief Summary of Prescribing Information, please see following page.

Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:

LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae* (formerly *Diplococcus pneumoniae*), other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli*, *Klebsiella* species, *Hemophilus influenzae*, and *Bacteroides* species.

GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli*, *Klebsiella* species, *Proteus mirabilis*, indole-positive *Proteus* (i.e., *P. morganii*, *P. rettgeri*, and *P. vulgaris*), and *Providencia* species. Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).

INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ and *Clostridium* species.

GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli*, *N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.

SEPTICEMIA caused by *Strep. pneumoniae* (formerly *D. pneumoniae*), *Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli*, *Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group.§

BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis*, streptococci (excluding enterococci, e.g., *Strep. faecalis*), *E. coli*, *P. mirabilis*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.

Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.

Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia; a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone; in more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.

Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.

Drug/Laboratory Test Interactions—High concentrations (>100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffé reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxy-corticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST ‖ reagent tablets.

Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.

Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers—Excreted in human milk. Exercise caution.

Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.

Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension. *Gastrointestinal*—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.

Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.

How Supplied: Sterile cefoxitin sodium in vials and infusion bottles containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles.

§ *B. fragilis*, *B. distasonis*, *B. ovatus*, *B. thetaiotaomicron*, *B. vulgatus*

PERSONALIZED LIBRARY CASES

Protect your personal copies of AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY in custom made, titled library cases.

Constructed of durable, reinforced binder's board covered in a rich simulated leather, each is designed to hold an entire year's issues. The Journal name is stamped in gold leaf, making the cases attractive additions to any decor, whether on your bookshelf, desk or any location in your home or office.

Only $7.95 each: 3 for $21.95; 6 for $39.95, and $1 per unit postage and handling ($2.50 per unit outside the U.S.A.). U.S. funds only.

To charge your order using American Express, Visa, MasterCard or Diners Club, call toll-free: 1-800-972-5858.

Here's what MOSBY'S BOUND VOLUMES can add to your practice!

MOSBY
TIMES MIRROR

Handsomely bound in durable buckram with rich gold stamping, bound journal reference volumes are important to every successful practice.

- gives quick and easy access to important journal articles
- eliminates problems with missing issues or pages
- makes your regular subscription a "working" copy to mark up, tear from, or file
- offers an inexpensive and easy way to guarantee bound reference volumes—prices include shipping

You Must Order Now!
Bound volumes are made up from over-run copies of each journal issue. You never worry about sending out your personal copies. But over-run quantities are limited. We need your order today! Bound volumes are only available to current subscribers and may not be ordered in place of a regular journal subscription. Payment must accompany your order.

TRI-LEVLEN™

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

A LOW-DOSE TRIPHASIC OC WITH THE CONFIDENCE THAT COMES FROM EXPERIENCE

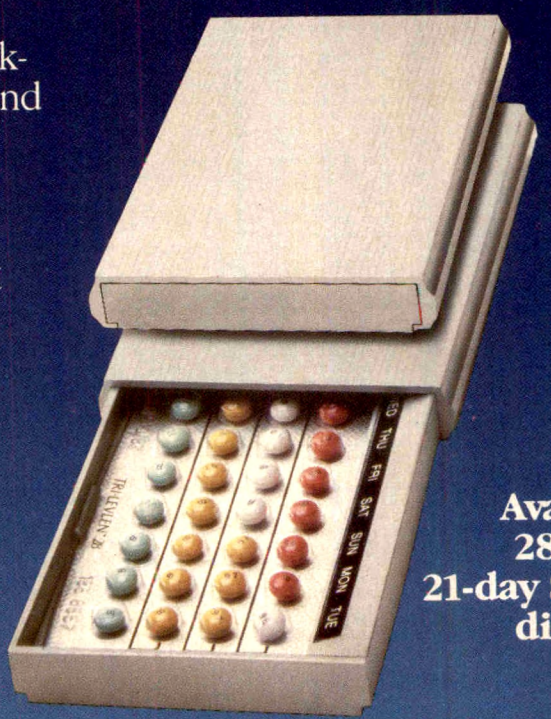
*Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptom of serious disease and discontinue oral contraceptive therapy when appropriate. These d represent only the results of selected studies. Therefore, before prescribing, the physician should read and remain alert to all data found in the complete prescribing information for the product. Please also see brief summary of prescribing information on the last page of advertisement.

A formulation with the lowest total hormonal dose in a combination OC

Phased doses of both levonorgestrel and ethinyl estradiol

Permits a decrease in total steroid dose without compromising effectiveness.

Minimal impact on the following metabolic and hemodynamic parameters*



Lipids;[2,3] carbohydrate metabolism[2,3] and blood pressure[1] were not significantly affected in certain specific studies.

Low incidence of breakthrough bleeding

A low 5.7% overall incidence of breakthrough bleeding based on 77 U.S. and U.K. studies involving 3,546 women (35,036 total cycles).[1]

Simple first dose/first day start

The first dose is taken on the first day of menstruation. No need to count days or wait for Sunday starts.

A formulation with the confidence of 170 million cycles of experience worldwide

Available in 28-day and 21-day Slidecase™ dispensers

TRI·LEVLEN™ 21

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

BRIEF SUMMARY

Tri-Levlen™—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings."

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted.: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information and package insert.

Chorioamnionitis: Its association with pregnancy outcome and microbial infection

P. A. Quinn, Ph.D., J. Butany, M.D., J. Taylor, M.D., and W. Hannah, M.D.

Toronto, Ontario, Canada

In a study of 33 cases of perinatal death, chorioamnionitis was observed in 57.6% compared with 5% of 20 control cases ($p < 0.001$) and in 70.8% of cases with no morphologic cause compared with 22.2% of cases with a defined cause of death ($p < 0.01$). Chorioamnionitis was significantly associated with previous gestations ($p < 0.01$), prolonged rupture of the membranes ($p < 0.001$), prematurity (20 to 27 weeks' gestation) ($p < 0.001$), and low birth weight (≤1000 gm) ($p < 0.001$) but not with elevated maternal white blood cell count or pyrexia. Overall, in patients with chorioamnionitis, the perinatal death rate was higher ($p < 0.01$); more stillbirths occurred compared with early neonatal deaths ($p < 0.05$), and there was a higher incidence of deaths with no defined cause ($p < 0.01$) compared with cases without chorioamnionitis. *Ureaplasma urealyticum* or pathogenic bacteria were isolated more frequently from villous tissue of placentas from cases with chorioamnionitis ($p < 0.01$) but not *Mycoplasma hominis, Chlamydia trachomatis,* or viruses. Furthermore, there was a higher prevalence of both elevated fetal antibody titer to *U. urealyticum* ($p < 0.025$) and fetal titers fourfold above maternal titers ($p < 0.05$) in cases with chorioamnionitis. The antibody responses and presence of microorganisms suggest that chorioamnionitis is associated with intrauterine infection and an associated increase in perinatal morbidity and mortality. (Am J Obstet Gynecol 1987;156:379-87.)

Key words: Chorioamnionitis, perinatal death, pregnancy outcome, microbial infection, *Ureaplasma urealyticum*

It has been believed that the intact placental membranes are a good barrier to ascending infections but this may be only partly true.[1] Depending on the study, reports indicate that between 5% and 40% of placentas show acute chorioamnionitis.[1, 2] Although the evidence for this has been equivocal, as microorganisms are isolated only in about 40% of cases,[2, 3] chorioamnionitis due to microbial infection is considered a significant cause of perinatal morbidity and mortality.[4] It is possible that the inability to culture mycoplasmas, viruses, chlamydia, anaerobes, and even some aerobes is due to inadequate sampling or improper culture techniques required for the isolation of these more fastidious microorganisms.

Often in examining a placenta histologically, one notes the presence of acute inflammatory cells in the amnion, chorion, or umbilical cord. The significance of these polymorphonuclear leukocytes is questioned, that is, are they related to premature rupture of the membranes or microbial infection, or are they nonspecific? It has also been said that the presence of polymorphonuclear leukocytes is common in the first and second trimesters of pregnancy and that their presence is nonspecific and not associated with pathogenic microorganisms.[3] However, the presence of polymorphonuclear leukocytes and acute chorioamnionitis may be due to different reasons. Our studies of perinatal death have shown a significant incidence of acute inflammation in the placenta and/or fetal lung in fatal cases compared with normal controls.[5] Second, this inflammation and the corresponding detection of bacteria and *Ureaplasma urealyticum* occurred primarily in fatal cases with no other recognized cause of death.

Previous studies examined either the placenta only[6-8] or the neonate.[9] In this study the placenta, fetus-neonate, and maternal and fetal blood were examined extensively. We undertook this study to determine whether there is an association between chorioamnionitis, microbial infection, and perinatal death on the basis of both perinatal deaths and normal term deliveries. Microbiologic and serologic tests were used to detect bacteria, mycoplasmas, viruses, and chlamydia.

Material and methods

Population studied. This prospective study was conducted at two University of Toronto teaching hospitals. All patients entered into the study were admitted either to Women's College Hospital (a hospital with a large high-risk pregnancy service and a regional perinatal unit) or to Toronto General Hospital, for delivery during the period June 1982 to February 1984. All patients were covered by a provincial health insurance plan. Cases of perinatal death included fetal death in utero after 20 weeks' gestation, or death of the neonate within 48 hours after delivery. The study included all consecutive cases with consent in which autopsy was performed on week days. The placenta was examined in detail and a complete autopsy performed. The majority of cases were cared for by obstetricians at the respective hospitals with details of the pregnancy easily obtained. In a minority of cases the patients were transferred to the Regional High-Risk Pregnancy Service (Women's College Hospital) just before delivery, and complete clinical histories could not be obtained.

The control group consisted of placentas taken from 20 random cases of normal term deliveries, occurring on weekdays, to accommodate laboratory services. The criteria for inclusion of cases as normal controls consisted of a term delivery with rupture of the membranes of <24 hours and no history of reproductive failure or problems in the current pregnancy. All clinical histories were reviewed to determine the presence of maternal fever, to evaluate the white blood cell count, and to check the duration of ruptured membranes.

For certain analyses the cases of perinatal death were divided into two groups: In group 1 were those with "anomalies" acceptable as a cause of death, such as multiple congenital abnormalities (Turner's syndrome) or severe hydrops fetalis with acute polyhydramnios, plus cases with a questionable anatomic cause of death, such as congenital abnormalities complicated by prematurity. There were no cases in which abruptio placentae was considered to be a significant factor. In group 2 were those with "no anomalies" (morphologic or anatomical) that would be considered the cause of death.

To examine the association of chorioamnionitis with pregnancy outcome and infection, the 53 cases were grouped and compared on the basis of the presence or absence of chorioamnionitis, as defined below.

Specimen collection. In the control group, samples of maternal and umbilical cord blood were collected at the time of delivery. A 3 cm cube of placenta was taken in the delivery suite with aseptic precautions and placed in a sterile container. All samples were taken to the microbiology laboratory as soon as possible and set up immediately. The placenta was sent to the department of pathology for histologic examination, and the fetus or neonate was submitted for autopsy. A maternal blood sample was requested. At autopsy, blood samples drawn from the fetus, placental tissue, and other postmortem specimens were submitted for microbiologic studies. A few cases were omitted when the fetus was severely macerated and the tissues badly autolyzed. If the fetus was of very low birth weight and the fetal blood sample could not be obtained or was hemolyzed, the case could not be adequately examined.

Pathologic examination. For the gross examination each placenta was weighed after "standardization," that is, the placental cake along with a 2 cm rim of membranes and 5 cm stump of umbilical cord. This was done to avoid differences in weight due to variations in cord lengths. The placenta, cord, and membranes were examined in detail. A comprehensive autopsy was performed in each case beginning with an external examination and followed by examination of the viscera.

Histologic examination. For histologic examination of the placenta, five blocks were taken from each placenta, including one strip of free membranes and umbilical cord and four full-thickness blocks of the placental cake. Histologic sections were stained with hematoxylin and eosin, and when evidence of inflammation was seen, sections were stained for bacteria (Gram and Gomori methenamine silver stains).

The histologic criterion used for acute inflammation of the placenta (chorioamnionitis) was the presence of accumulations of polymorphonuclear leukocytes extending through the fetal membranes and/or the umbilical cord.[10] Polymorphonuclear leukocytes were generally seen in the chorionic plate, under the amnion, and at times in the intervillous space under the chorionic plate.[10] All histologic sections of the placenta were examined by one of us without knowledge of the microbiologic findings (J. B.).

Microbiologic methods. The placental tissue was surface sterilized by burning with alcohol and cut open through the chorionic surface. A block of villous tissue was removed from the inside for culture to avoid surface contamination and obtain an indication of microorganisms actually present in the placental substance. For bacteria, this piece of placenta was minced lightly; a Gram stain was done, and the specimen was inoculated on media to isolate aerobic and anaerobic bacteria and fungi as previously described.[5] For mycoplasmas, the tissue specimens were lightly minced, not ground, and inoculated into two broth and agar culture systems for the isolation of large colony mycoplasmas and *U. urealyticum*.[5] Three tenfold serial dilutions were made for broth cultures. All negative cultures were blind passaged on days 3 and 7 and incubated for 21 days. All medium components and each medium batch were routinely quality controlled for adequate growth-promoting capacity. Tissues were frozen at −70° C in transport media containing gentamicin (10 μg/ml),

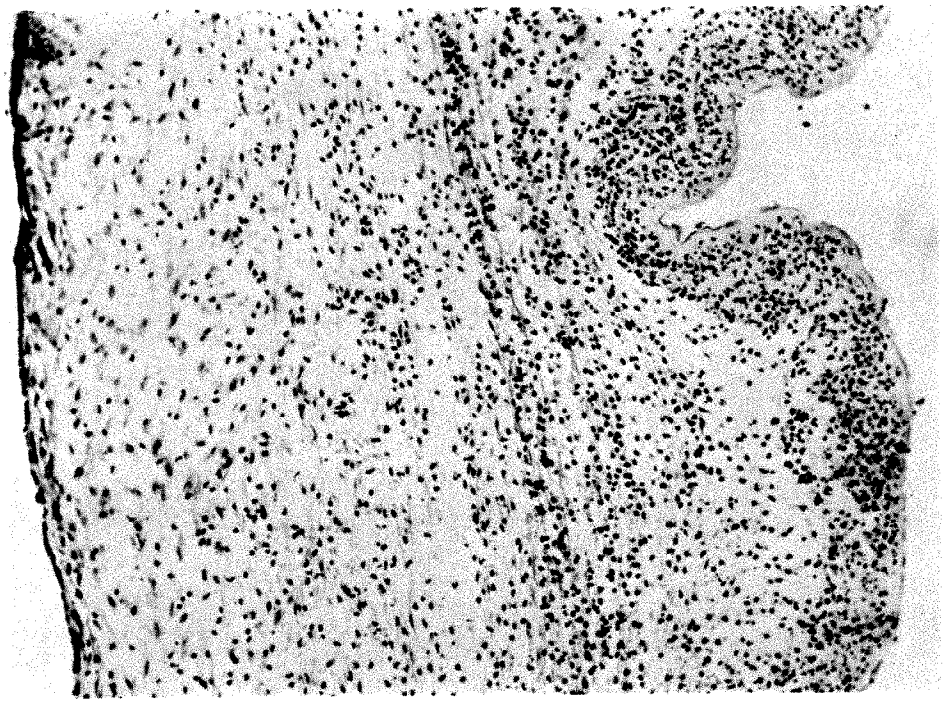

Fig. 1. Acute chorioamnionitis. Histologic section of the fetal surface of the placenta showing acute chorioamnionitis. There is an infiltration of the amnion and the chorion by polymorphonuclear leukocytes. (Original magnification ×100.)

streptomycin (50 μg/ml), and nystatin (25 μg/ml) for the isolation of chlamydia in cycloheximide-treated HeLa cells.[11] The tissues were frozen at −70° C and set up for the isolation of viruses in skin fibroblasts, green monkey kidney, and HeLa 293 cells.[11]

Serologic methods. A modified metabolic inhibition test[12] was used to measure the patient's antibody response to eight serotypes of *U. urealyticum* and *Mycoplasma hominis* strain PG-21. Any sera showing nonspecific inhibition to all serotypes was excluded. Antibody titers to *Chlamydia trachomatis* were detected by the microimmunofluorescence test.[13] The hemagglutination test was used for rubella, the complement fixation test for cytomegalovirus and herpes simplex virus, and the neutralization test for enterovirus and coxsackie virus B.[11] For *U. urealyticum* an antibody titer of ≥1:32, for *M. hominis* a titer of ≥1:8, and for chlamydia and viruses a titer ≥1:64 was scored as elevated. Rubella-positive titers were excluded. When limited sera were available, priority was given to the mycoplasma titers.

Statistical methods. Comparisons were made between chorioamnionitis-positive versus chorioamnionitis-negative placentas. In each test of significance, the χ^2 test, corrected for continuity, was used. For groups with small numbers, Fisher's exact test was used and performed at a 5% level of significance in both tails of the distribution. For borderline values, the exact p value is given.

Results

Chorioamnionitis in cases of perinatal death versus controls. Of the 53 placentas examined, chorioamnionitis was found in 20 (Figs. 1 and 2). Since there was greater evidence of infection in cases of perinatal death,[5] the significance of placental chorioamnionitis was assessed. The data presented in Table I clearly show a higher incidence of 57.6% in cases with chorioamnionitis in the perinatal death group compared with 5% in the control group ($p < 0.001$). The perinatal deaths were then divided into two groups, those with "anomalies" that were a possible cause of death and those with "no anomalies" or no morphologic cause of death. Among those with no anomalies, chorioamnionitis was observed in 74.9% of cases compared with 12.5% of cases with no anomalies ($p < 0.01$).

Among the cases of perinatal death examined for the presence of microorganisms, *U. urealyticum* was isolated from 57.9% and pathogenic bacteria from 26.1% of placentas compared with 10% and 0%, respectively, in control placentas ($p < 0.01$ and $p < 0.05$). There were no significant isolations of *M. hominis*, viruses, or *C. trachomatis*. When the perinatal deaths were assessed, most of the *U. urealyticum* isolations came from placentas in the group with no congenital anomalies ($p < 0.05$). The isolation of pathogenic bacteria and *M. hominis* occurred more often in the same group but was not statistically significant.

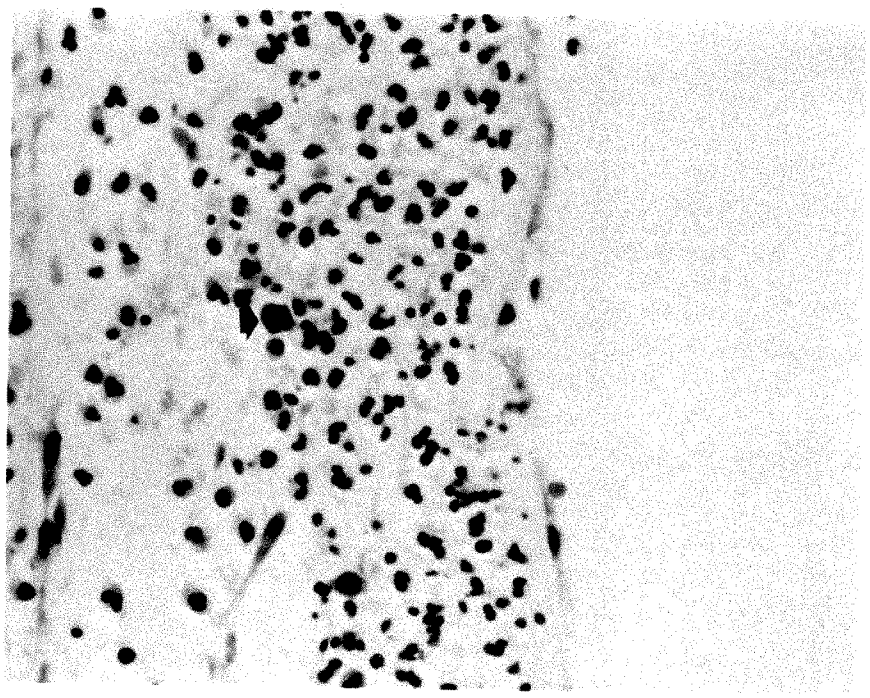

Fig. 2. Higher magnification of Fig. 1 shows that most of the inflammatory cells are polymorphonuclear leukocytes with a few macrophages *(arrowhead)*. (Original magnification ×400.)

Table I. Incidence of microorganisms isolated from the placenta: Perinatal deaths versus controls

Status	*Chorioamnionitis positive*	*Pathogenic bacteria*	*Mycoplasmas*		*Viruses*	*Chlamydia*
			U. urealyticum	M. hominis		
Control	1/20	0/20	2/20	0/20	ND	0/20
Perinatal death	19/33	6/23	10/23	1/23	0/10*	0/9*
p Value	<0.001	<0.05	<0.01	NS	–	NS

No anomalies	17/24	5/18	10/18	1/18	0/6	0/6
p Value	<0.01	NS	<0.05	NS	NS	NS

ND = Not determined.

*In four cases the tissues were toxic to the cell cultures.

These observations support the concept that chorioamnionitis associated with *U. urealyticum* and pathogenic bacteria are important factors in perinatal death, particularly among the 72.7% of cases with no other morphologic cause of death. In addition, when the surface of the placenta is carefully decontaminated, few bacteria are isolated, and only 10% of control placentas from normal term delivery with no previous history of reproductive failure have *U. urealyticum* in our population.

Correlation of chorioamnionitis with obstetric history. The obstetric history of patients with and without chorioamnionitis is outlined in Table II. Among the 53 patients studied, 20 had chorioamnionitis and 33 did not. Chorioamnionitis was observed significantly more often in women with previous pregnancies than in primigravid patients. There was no difference in the number of previous losses or previous living children with this size population.

Correlation of chorioamnionitis with gestational age and birth weight. The distribution of gestational age and birth weight is examined in Table III. There was a significantly higher number of very premature fetuses (20 to 27 weeks' gestation) among women with chorioamnionitis ($p < 0.001$) and correspondingly with birth weights <1000 gm ($p < 0.001$) than among the women with normal placentas. In the chorioamnionitis-negative group, 66% of the fetuses-neonates were >38 weeks of gestational age, and 69.6% had birth weights ≥2500 gm. Since all the control infants and many of the stillborn infants with congenital anomalies were delivered near term and were mainly chorioamnionitis

Table II. Correlation of chorioamnionitis with obstetric history

			Multigravid women		
	No.	*Primigravid women*	*No.*	*No. of previous losses*	*No. of previous living children*
Chorioamnionitis positive	20	3	17	11	6
Chorioamnionitis negative	33	18	15	7	2
p Value			<0.01	NS	NS

Table III. Correlation of chorioamnionitis with gestational age and birth weight

		Gestational age				*Birth weight*		
	No. of cases	*20-27 wk*	*28-31 wk*	*32-37 wk*	*≥38 wk*	*≤1000 gm*	*1001-2499 gm*	*≥2500 gm*
Chorioamnionitis positive	20	14	2	3	1	16	2	2
Chorioamnionitis negative	33	5	4	2	22	4	6	23
p Value		<0.001	NS	NS		<0.001	NS	

Table IV. Correlation between chorioamnionitis and clinical parameters

	Elevated white blood cell count		*Pyrexia*		*Prolonged rupture of membranes (≥24 hr)*
	≥11 × 10⁹/L	*≥13 × 10⁹/L*	*≥37.5° C*	*≥38.0° C*	
Chorioamnionitis positive	12/19	7/19	5/20	4/20	10/19
Chorioamnionitis negative	15/31	5/31	9/33	3/33	1/32
p Value	NS	NS	NS	NS	<0.001

negative, the higher gestational ages and birth weights would be expected.

Correlation of chorioamnionitis with clinical parameters. Clinical evidence of chorioamnionitis may include elevated white blood cell count and pyrexia. In this population there was no significant elevation in white blood cell count, even at ≥13 × 10^9/dl, or pyrexia among chorioamnionitis-positive compared with chorioamnionitis-negative women in Table IV. However, chorioamnionitis did occur significantly more often in women with rupture of the membranes of ≥24 hours ($p = 0.00013$). Thus, in this study, elevated white blood cell count and pyrexia were not significant indicators of underlying chorioamnionitis. On the other hand, in 10 patients with prolonged rupture of the membranes, five had white blood cell counts of ≥13 × 10^9/dl, and three had pyrexia. There seems to be more of an association with clinical evidence of infection in bacteria-positive cases than in mycoplasma-positive cases.[5] At most, 26% of women in the group with chorioamnionitis and none of the control subjects had evidence of "clinical" infection before delivery.

Correlation of chorioamnionitis with pregnancy outcome. The population studied included fetal-neonatal deaths and normal term neonates. When the pregnancy outcome is examined in relation to chorioamnionitis, one would expect an even distribution of outcomes; that is, neonatal deaths or congenital anomalies would occur equally in each group. This was the case among the chorioamnionitis-negative group, as shown in Table V, the number that survived versus the number that died and the number of neonatal deaths versus the number of stillbirths being about equal. However, among the chorioamnionitis-positive cases significantly more deaths occurred ($p < 0.01$), and more were associated with stillbirth ($p < 0.05$) than with early neonatal death.

Correlation of chorioamnionitis with isolation of microorgansims. To determine the correlation between chorioamnionitis and the presence of microorganisms, a wide spectrum of cultures was done on the villous tissue to obtain a true indication of microorganisms actually in the placental tissue. Two approaches were used to address the question; higher virulent strains only and all bacteria isolated were used in the analyses. As outlined in Table VI, *U. urealyticum* and/or pathogenic bacteria were isolated more often from the placenta in chorioamnionitis-positive cases than in negative cases ($p < 0.01$). Analysis of a greater number of cases is required to clarify the status of each alone.

Table V. Correlation between chorioamnionitis and pregnancy outcome

	No. surviving	*Died*			*Cause of death*	
		No.	*Neonatal death*	*Stillbirth*	*With anomalies*	*Without anomalies*

Chorioamnionitis negative	8/29	12/25	9/26	3/28	2/26	5/20	5/20	3/20	2/20
p Value	<0.025	<0.05	NS	NS	NS	NS	NS	NS	NS

*Elevated titer taken as ≥1:32 to one or more *U. urealyticum* serotypes 1 to 8.
†Elevated titer taken as ≥1:8 to the standard strain PG-21.
‡Elevated titer taken as ≥1:64 for viruses and chlamydia.

Among the five cases considered to have pathogenic bacteria, one had β-hemolytic streptococci, Lancefield group B, alone, one had *Staphylococcus aureus, Pseudomonas aeruginosa,* and *Bacteroides melaninogenicus;* and one each had *Citrobacter freundii* and *B. melaninogenicus. M. hominis* was isolated only once from a control patient. Overall either pathogenic bacteria and/or *U. urealyticum* isolated from 71.4% of chorioamnionitis-positive cases compared with 27.6% of chorioamnionitis-negative cases ($p < 0.01$). The combined presence of these organisms was previously documented.[5] Viruses or chlamydia were not isolated from the placenta in this study. In our experience, *C. trachomatis* has been isolated only once from 250 placentas cultured. This occurred in a term pregnancy in a patient with successful management of premature onset of labor (unpublished observations). These observations suggest that there is a correlation between the presence of inflammation in the placenta and the isolation of *U. urealyticum* and pathogenic bacteria.

Among the chorioamnionitis-negative group there were six additional cases in which strains considered to be of low virulence were isolated. These included one with *Streptococcus faecalis, Staphylococcus epidermidis,* and *Candida albicans,* one with *S. epidermidis* and enteric streptococci, and ones with *Bacteroides vulgaris, Clostridium* sp., *Streptococcus viridans,* and *Escherichia coli.* In all cases, these yielded only a few colonies, compared with a heavy growth of the more pathogenic stains. If the presence of all bacteria is included, there is no significant difference in the isolation rate, 28.6% versus 24.1%, between chorioamnionitis-positive and -negative cases. Perhaps the specific species, the actual concentration of organism, the location of bacteria, and the combination of bacteria with *U. urealyticum* are the important factors in understanding the association of chorioamnionitis with microorganisms.

Correlation of chorioamnionitis with elevated antibody titers. Another aspect of examining fetal-maternal infection was to assess the antibody responses in cases with and without chorioamnionitis. As shown in Table VII, the prevalence of elevated antibody response to *U. urealyticum* at a titer of ≥1:32 was 75.0% in fetuses from pregnancies with chorioamnionitis com-

pared with 27.6% in control pregnancies ($p < 0.025$). The prevalence of elevated ureaplasma antibody in the mothers with chorioamnionitis was 57.1% compared with 34.6% in those without (NS). Since maternal immunoglobulin G could cross to the fetus, the prevalence of a fourfold higher fetal titer above the maternal titer, suggestive of fetal immunoglobulin M response, was determined. Among chorioamnionitis-positive cases with complete serologic evaluation, the fetus had a four times higher titer than the mother in 100% of the cases compared with 48% in the chorioamnionitis-negative cases ($p < 0.05$). These observations suggest that in cases of chorioamnionitis, the fetus produces antibody indicative of intrauterine infection with *U. urealyticum*. In cord sera from normal term gestations, only 6.5% of neonates have titers $\geq 1:32$ and 2.2% have titers fourfold above maternal levels.[12]

An antibody response to *M. hominis* with the use of the metabolic inhibition test and strain PG-21 was detected in five cases, all controls. This correlates with the low isolation rate of *M. hominis* in this study. On the other hand, the use of strain PG-21 may not be adequate to detect antibody responses to all serotypes (Quinn PA, et al., paper presented at the Sixth International Congress of the International Organization for Mycoplasmology, Birmingham, Alabama, August 22-31, 1986). An elevated fetal and maternal antibody response to viruses and chlamydia ($\geq 1:64$) occurred more often in the chorioamnionitis-negative group than in the positive group.

Comment

Whether the inflammatory response observed in the placenta is due to infection is a much debated point. Infection can occur through intact membranes with monilia,[3] *U. urealyticum*, and *M. hominis*[14] resulting in clinically silent chronic intrauterine infection characterized by an intense inflammatory response. Infection can also occur with rupture of the membranes as extensively documented.[3]

In determining the cause of perinatal death, no morphologic cause can be documented at autopsy of the fetus in nearly two thirds of cases.[4, 5, 15] Naeye et al.[10] reported that acute chorioamnionitis occurred in 53% of stillbirths and early neonatal deaths. Among these chorioamnionitis-positive cases, 45 of 48 infants were born prematurely and 42 of 48 died in the perinatal period, of causes associated with prematurity and no anatomic cause of death.[19] In our previous studies, an increased incidence of inflammation in the placenta and/or fetal lung and a higher isolation rate of *U. urealyticum* were observed in perinatal deaths compared with controls, especially among those with no anatomic cause of death.[5]

In the present study, chorioamnionitis was observed in 57.6% of 33 perinatal deaths, and only 5% of normal term deliveries among women carefully documented to have no previous history of pregnancy loss or premature delivery. Furthermore, 70.8% of chorioamnionitis-positive placentas occurred among cases with no cause of death versus 22.2% of cases with other causes. Although evidence of infection is observed more often in cases with no clear-cut cause of death, it is also seen in 20% of those with other problems. Perhaps in the latter cases the infection is a contributing factor in the death of the fetus. These observations all support the concept that chorioamnionitis associated with *U. urealyticum*, alone or in combination with bacteria, is a major factor in intrauterine infections associated with perinatal morbidity and mortality.

What causes chorioamnionitis is a controversial subject because of the diversity of microorganisms isolated, often of low virulence,[4, 6, 8] and the concept that nonspecific placental inflammation may occur.[3] It has been reported that a significantly higher rate of poor outcomes occurred when genital mycoplasma, particularly *U. urealyticum*, were isolated from placentas.[8] Isolation of *U. urealyticum* has been associated with an increased incidence of chorioamnionitis, low birth weight, spontaneous abortion, and stillbirth, as well as early neonatal death and morbidity, but not prolonged rupture of the membranes.[5, 8, 14] The latter observation fits with the concept of a chronic, silent chorioamnionitis occurring before rupture of the membranes with genital mycoplasmas.[14]

Pankuch et al.,[6] in a study looking for aerobic and anaerobic bacteria and chlamydia, found positive bacterial cultures in 72% of placentas having evidence of chorioamnionitis while only 15% of placentas not having histologic evidence of chorioamnionitis had positive cultures. About 50% of their positive cultures were associated with anaerobic bacteria. In our previous report on microbial infection in perinatal deaths,[5] one of the most significant findings was that the perinatal deaths were associated with a mixed spectrum of bacteria, genital mycoplasma, and viruses. In only one of 12 bacteria-positive cases were no other organisms isolated. However in 11 of 20 mycoplasma cases no other bacteria were found. As our data and Naeye's[4] suggest, diverse microorganisms, perhaps of lower virulence but in combination with for example *U. urealyticum*, may be significant. Overall, we found that 71.4% of chorioamnionitis-positive cases had *U. urealyticum* or other pathogenic bacteria without strict anaerobic cultures being done, compared with 17.6% of the chorioamnionitis-negative cases. Thus the actual incidence of microorganisms in chorioamnionitis-positive placentas may be even higher than 72% if cultures could be done for all fastidious organisms at once.

On the other hand, in the studies of Svensson et al.,[7]

no correlation between chorioamnionitis and bacteria were found in placentas with delivery by cesarean section. The authors did not clearly set out the indications for the cesarean sections nor did they give the exact duration of pregnancy, except that in 18 cases the delivery was premature (before the thirty-seventh week). If organisms such as *U. urealyticum* are associated with spontaneous loss and prematurity, then the control population should have no previous history of problems that may be associated with infection. However, histologic chorioamnionitis did correlate with maternal or neonatal infection. In their study, the placental surface was not decontaminated. Few details were given on how *M. hominis* was isolated and no details were given for the isolation of *U. urealyticum*. This is a crucial point because mycoplasmas are not readily isolated from ground tissue commonly used to detect bacteria.[16] They reported that in no cases were *U. urealyticum* or *M. hominis* isolated and only 14% of patients had cervical cultures that were positive for ureaplasmas. This incidence appears very low since reports on female colonization with *U. urealyticum* vary from 20% to 80% of pregnant women.[16] In our studies, *U. urealyticum* is isolated from 10% of the placentas of normal deliveries among women with no previous history of pregnancy loss or prematurity[5] and 20% of any term gestations (Grundman H, Milligan J, Shennan A, et al. The association of *Ureaplasma urealyticum* with preterm birth, presented at the Forty-second Annual Meeting of The Society of Obstetricians and Gynaecologists of Canada, Charlottetown, Prince Edward Island, June 23-27, 1986). When we analyzed all cases with bacteria isolated, including those with scanty growth of any organisms, we also found no association with chorioamnionitis. Perhaps the key to understanding the association of microorganisms in chorioamnionitis is to examine not only the bacterial species isolated but also their concentration and presence with other organisms such as *U. urealyticum*.

Mueller et al.,[15] in a study of 124 stillbirths or early neonatal deaths, reported that only 35% had structural physical abnormalities associated with achromosomal, single-gene, or polygenic disorders. Thus histologic examination of tissues obtained at autopsy is not necessary. In view of the high yield of chorioamnionitis in our study cases and its association with positive cultures, we feel that it definitely is of value. We agree with Naeye[4] that histopathologic analysis of autopsied tissues, particularly the placenta, can provide answers to many questions. In addition to providing a morphologic explanation for the perinatal loss, it can help to assuage the family's feeling of guilt about their role (if any) in the stillbirth. This in itself is significant when no cause of death is found in 65% to 70% of cases.[5, 15]

In such studies of human disease one cannot prove causation but only observe and accumulate supportive evidence. The isolation of organisms does not prove that they cause the pathologic lesion or fetal death. However, isolation of an organism, evidence of an inflammatory response in the placenta, and development of a fetal antibody response are strong evidence of infection in a given pregnancy, indicative of an association between the presence of infection and the stillbirth. The strongest evidence comes from the bovine model, where *Ureaplasma diversum* is also associated with reproductive failure, endometritis, and salpingitis. When *U. diversum* was experimentally inoculated into the amniotic fluid of pregnant heifers, it induced abortion and premature delivery of a calf with only respiratory disease in all cases.[17, 18] The calves exhibited patchy alveolitis similar histologically to that reported in humans.[19] These data certainly prove that in bovines, *U. diversum*, a very closely related species, causes infection in pregnancy, leading to spontaneous abortion, placentitis, and prematurity with neonatal respiratory disease.

In conclusion, our study shows that chorioamnionitis is a significant finding in cases of stillbirth. In a large number of cases it is associated with positive cultures of *U. urealyticum* and pathogenic bacteria, which often occur together.[5] Chorioamnionitis is also positively associated with a significant incidence of prematurity, low birth weight, and a poor outcome of pregnancy. On the basis of our results, we strongly recommend that in all cases of perinatal death a complete autopsy, including examination of the placenta, be done. In each case comprehensive cultures of the placenta and serologic studies on maternal and fetal blood, where possible, should be an integral part of the investigation. Only in this manner can we get a clearer picture of the pathogenesis of chorioamnionitis and develop methods to diagnose and treat such women before the pregnancy is lost.

We wish to thank the obstetricians at Women's College Hospital and Toronto General Hospital for the use of their cases. The expert technical assistance of A. Yau, H. C. S. Li, S. Mitra, and D. Askew, in the Department of Bacteriology, and the staff in the Department of Virology at The Hospital for Sick Children and the Department of Microbiology at Women's College Hospital is much appreciated.

Massive genital and vaginal vault prolapse treated by abdominal-vaginal sacropexy with use of Marlex mesh: Review of the literature

Harold P. Drutz, M.D., and Lily S. Cha, M.D.
Toronto, Ontario, Canada

Two patients with massive procidentia and 13 patients with posthysterectomy vaginal vault prolapse underwent surgical procedures at Mount Sinai Hospital, Toronto, between May 1978 and February 1986. The standard procedure consisted of an abdominal sacropexy, with use of Marlex mesh to anchor the vaginal vault to the sacral promontory and retroperitonealization of the mesh. In 11 of the 15 patients, one or more concurrent procedures were performed at the same time. There were no intraoperative complications. One serious postoperative complication occurred, and one patient developed recurrent vault prolapse. Follow-up has been from 3 to 93 months with an average of 28 months. In 14 patients (93.3%) subjective and objective improvement was achieved. A review of the literature is presented (Am J Obstet Gynecol 1987;156:387-92.)

Key words: Vault prolapse, abdominal sacropexy, Marlex

Genital and vaginal vault prolapse is a distressing problem for the patient and the gynecologist. Besides causing discomfort with sitting, walking, and intercourse, vault prolapse interferes with bladder function and predisposes the patient to recurrent urinary tract infections and possible renal problems by ureteral obstruction.

Apart from the use of supportive pessaries, treatment is surgical. The aim in correction is to (1) restore the normal vaginal axis, (2) maintain existing vaginal length, and (3) provide permanent cure. Review of the literature reveals that there have been no less than 43

well-documented descriptions of operations for vaginal vault suspension.[1] Materials used for suspension have varied considerably: external oblique fascia, fascia lata, Mersilene, Marlex (Davol Rubber Co., Providence, Rhode Island), and Teflon meshes.

This article reviews the results of some of these operative procedures and describes one technique for correction of vaginal vault prolapse. It also demonstrates how correction of other genitourinary defects can be performed at the same time.

Material and methods

Two women with massive genital prolapse and 13 women with posthysterectomy vaginal vault prolapse underwent corrective operations between May 1978 and February 1986. The average age was 61.8 years (range: 47 to 82 years) and the average parity was 3.2 (range: 0 to 8). All patients were healthy and active, and 13 of the 15 patients had undergone one or more

previous gynecologic operations (Table I). In all, 30 gynecologic procedures had been performed on the 13 patients before their admission for abdominal sacropexy. The two women who had not undergone a previous gynecologic operation both had massive procidentia with uterus and vagina prolapsed well beyond the introitus, producing masses the size of watermelons. Both women had extracorporeal bladders, and one patient developed bladder calculi from chronic urinary stasis. Prior to vaginal vault suspension, both women required total abdominal hysterectomy, partial vaginectomy, and retropubic colpourethropexy.

Prophylactic antibiotics were used at the discretion of the senior author (H. P. D.). Seven patients received no prophylaxis, while eight patients received various antibiotics before and after the operation. Three of these eight patients had medical indications for prophylactic antibiotics (mitral valve prolapse) (Table II).

Operative technique. While under general anesthesia, the patient was placed in the lithotomy position for insertion of a Foley catheter. The vagina was packed with a vaginal roll soaked in Proviodine. The patient was then placed in the supine position for cleansing and draping of the abdomen. If a retropubic colpourethropexy was planned, the patient was placed in the semilithotomy position.

Concurrent procedures planned along with the vault suspension were performed first. Thus eight patients had retropubic colpourethropexies, four had internal anterior repairs (an equilateral triangle, approximately 5 cm on each side, was excised from the anterior vaginal wall through the abdomen, the redundant bladder base was plicated, and the vaginal walls were closed with a running locked 1-0 chromic suture), two had abdominal hysterectomies, and three had partial vaginectomies.

For the vaginal vault suspensions, the vaginal vault was freed up by dissecting the bladder anteriorly and the posterior peritoneum inferiorly. Three to four 1-0 Tevdek sutures (Deknatel, Queens Village, New York) were placed in the posterior aspect of the vagina, with care taken not to penetrate the mucosa. A piece of Marlex mesh, approximately 5 by 8 cm, was attached to the vagina with the aid of the sutures. Next the rectum and sigmoid colon were mobilized to the left, and the parietal peritoneum over the sacral promontory was incised longitudinally. Care was taken to expose the median sacral artery and vein and to identify the right ureter and iliac vessels, thereby avoiding operative injury. Three to five Tevdek sutures were placed through the anterior longitudinal ligament of the spine, and these were attached to the other end of the mesh. The mesh was trimmed and the peritoneum closed over the mesh (Figs. 1 and 2). The peritoneum over the paracolic gutters was also closed with 2-0 chromic suture.

In one patient, A. P., the vaginal vault was so long that it readily reached the sacral promontory. The presacral peritoneum was not opened, and the sutures were placed directly through the peritoneum into what was thought to be the ligamentous tissue covering the sacrum without using any mesh.

Results

All operations were performed by one of us (H. P. D.). Follow-up time is 3 months to 93 months (mean, 28 months). There was one surgical failure in the patient who had the vaginal vault suspension

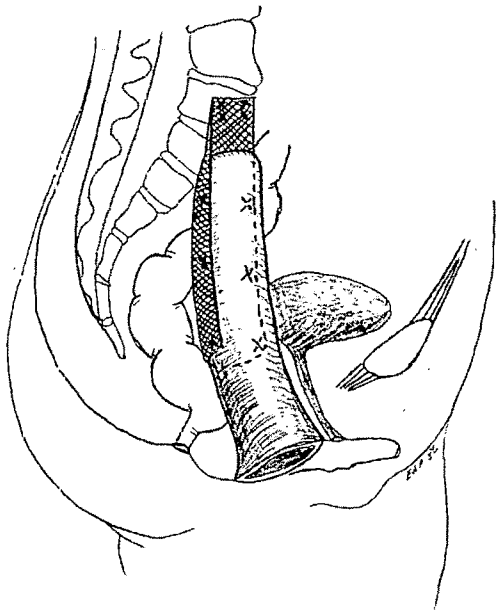

Fig. 1. Sagittal view showing mesh fixed to back of vagina and anchored to presacral fascia.

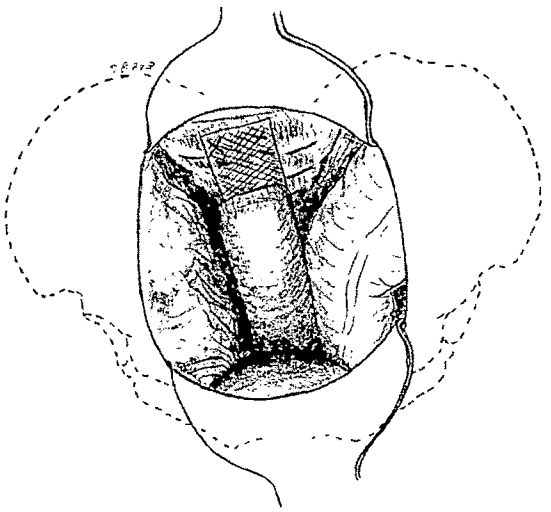

Fig. 2. View from above of vagina suspended to presacral fascia by Marlex mesh.

without mesh and without opening of the presacral peritoneum (A. P.). Vaginal vault prolapse recurred 6 months after operation. This patient was subsequently operated upon at another center, where an obliterative vaginal procedure was performed which corrected the defect but left her with a shortened nonfunctioning vagina.

One postoperative complication developed 3 weeks after operation in a patient who had a retroperitoneal colpourethropexy and vaginal vault suspension (W. E.). Fever and abdominal pain prompted a gallium scan, which showed bilateral retroperitoneal collections of pus. At operation, pus was evacuated from both iliopsoas muscles retroperitoneally, and cultures subsequently produced *Escherichia coli*. The Marlex mesh appeared free from the infectious process but was removed, since being a foreign body, it was thought to be a potential nidus of infection. The patient fully recovered, and the vaginal vault remained suspended.

Two patients developed small enteroceles and rectoceles. These did not cause any symptoms and have not been treated surgically.

Two patients with massive genital prolapse did very well postoperatively, and at follow-up 2 years after their operation, had well-supported vaginal vaults (Table III).

Use of prophylactic antibiotics appeared to decrease the incidence of febrile morbidity although not to a statistically significant degree. The infections in the retroperitoneal space and the abdominal wound occurred in patients who did not receive prophylactic antibiotics. At this point in time it is our clinical impression that prophylactic antibiotics should be used in this type of operation.

Comment

The present series of patients with vaginal vault prolapse represents an ongoing evaluation of the technique of abdominal suspension with use of Marlex mesh. The basic surgical technique has been described previously. Lane[2] reported four patients in whom Marlex mesh was used in vaginal vault suspension, but only the distal ends of the mesh were retroperitoneal, predisposing the patient to bowel obstruction. Soichet[3] described two patients in whom he buried the mesh completely, and Grundsell[4] reported 11 patients in whom Marlex mesh was placed retroperitoneally to suspend the vault. He attained excellent results (no recurrences, one cystocele).

Javey[5] described a completely extraperitoneal abdominovaginal operation for vaginal inversion, with use of Mersilene mesh in 13 patients without complications.

In our series the sacral promontory is used as the site of fixation because it is technically easier to place sutures through the anterior longitudinal ligament at this level. No problems with hemorrhage were encountered.

Suture placement at the hollow of the sacrum (S2-4)[6, 7] is complicated by the presence of presacral venous and nerve plexus, and life-threatening hemorrhage has been reported during this procedure.[8]

It has been shown by Nichols[9] that the vaginal axis assumes an almost horizontal plane in its upper two-thirds, where it lies on top of the rectum and levator plate. When attached to the sacral promontory, the vagina can still assume a normal axis because the mesh is not pulled taut.

Table IV. Review of literature

Authors	Year of publication	Procedure	No. of cases	Follow-up	Success		Significant complications
					n	%	
Lane	1962	Abdominal	20	Not reported	18/20	90	Not reported
Birnbaum	1973	Abdominal Vaginal	9 8	1-18 yr	9/9	100	7/8 = 87.5% nonfunctioning vagina; 1 incontinence

Grundsell	1984	Abdominal	9	Average, 3.9 yr	9/9	100	1 cystocele
Drutz, Cha	1987	Abdominal (Marlex)	15	3-93 mo; average, 28 mo	14/15	93.3	1 recurrent prolapse, 1 retroperitoneal abscess

Other techniques of posterior vaginal vault suspension have tried to restore the normal vaginal axis. Transvaginal fixation of the vault to the sacrospinous ligament[10, 11] (usually the right) restores the vaginal axis, but the technique can be fraught with difficulties. "Blind" placement of sutures can predispose the patient to injuries of pudendal vessels, sciatic nerve, urinary tract, and rectum. Also, the vagina may be shortened, impairing sexual function.[6] In the skilled hands of Nichols, however, this technique has given good results with few complications. Transvaginal fixation of the vault to the sacrotuberous ligament has been used infrequently because of its technical difficulty.

Table IV summarizes the results of these techniques of posterior suspension of the vaginal vault. Nichols[11] reported 12 complications in 163 patients including three patients with shortened vaginas, five with recurrent prolapses, two with sciatic nerve trauma, and one with laceration of the rectum. One patient died as a result of postoperative pulmonary embolism. In a series of 97 patients, Richter[10] reported two recurrent vault prolapses and 29 patients who subsequently developed enterocele, rectocele, or urinary incontinence. Birnbaum[6] had no recurrent case of vault prolapse, but one patient developed urinary incontinence. Grundsell[4] had complete success with his procedures, and only one patient of nine developed a cystocele. Lane[2] reported no complications in his short follow-up.

In summary, we feel that abdominal sacropexy is an excellent technique for the treatment of vaginal vault and massive genital prolapse. The advantage of an abdominal versus a vaginal approach is seen in less intraoperative injury to vessels, nerves, and bowel, since sutures can be placed under direct vision. Also, the abdominal approach allows for retention of vaginal length and strengthening of the pelvic floor and cul-de-sac. Coexisting defects of the vaginal wall can be corrected by internal anterior and/or posterior repair, and retropubic colpourethropexy can be performed for stress urinary incontinence at the same surgical setting. Marlex mesh has proved to be a strong and reliable synthetic bridge which we use frequently in suburethral slings and combined abdominovaginal slings for recurrent stress urinary incontinence; it has not previously been reported as a cause of infections.

Sacrococcygeal teratoma: Prenatal diagnosis and management

Susan J. Gross, M.D., Ronald J. Benzie, M.B., Ch.B., Mathew Sermer, M.D., Martin B. Skidmore, M.B., and Stephanie R. Wilson, M.D.

Toronto, Ontario, Canada

Although sacrococcygeal teratoma is a rare and potentially malignant tumor, 10 cases were documented during a 5-year period at the University of Toronto Perinatal Complex. Diagnosis was made in the six cases in which prenatal ultrasound examination was performed. One patient with twins elected to terminate the pregnancy at 19 weeks. In three of the cases diagnosed prenatally, serial ultrasound was performed. There was a 75% cesarean section rate. In all cases diagnosed prenatally, the large tumor size affected the mode of delivery. In the four cases without prenatal diagnosis, two infants were delivered vaginally, and two were delivered abdominally for obstetric reasons. There was one case of neonatal morbidity where tumor vascularity and rupture resulted in hypovolemic shock. All tumors were resected and found to be benign. A plan of management is recommended and, with appropriate obstetric and pediatric care, a good outcome can be anticipated in most cases. (AM J OBSTET GYNECOL 1987;156:393-6.)

Key words: Teratoma, sacrococcygeal, pregnancy

Sacrococcygeal teratoma is a congenital tumor arising from all three germ cell layers. It has an incidence of one to two per 40,000 deliveries[1] with only isolated reports in the literature. The importance of neonatal diagnosis is twofold. Ten percent of these tumors may be malignant at the time of delivery.[2] They may grow to a large size, affecting fetal outcome and labor management. The objectives of this study were to examine the prenatal diagnosis and the antepartum and intrapartum management with subsequent outcome.

Methods

Cases of sacrococcygeal teratoma during a 5-year period (from 1980 through 1985) from four tertiary referral centers forming the University of Toronto Perinatal Complex were studied retrospectively. Six cases, including one set of twins, originated from the complex itself, while four were referred from outlying hospitals. Prenatal assessment, diagnosis, fetal weight and sex, size of tumor, mode of delivery, and outcome were documented. A diagnosis of sacrococcygeal teratoma required histologic confirmation.

Results

A total of 10 cases were recorded, with one set of female twins and a female:male ratio of 9:1. In six of the cases, ultrasonographic diagnosis of sacrococcygeal teratoma was made, a large-for-dates uterus being the indication for the ultrasound examination. No other phenotypic abnormalities were identified although there were three cases of polyhydramnios. Because of prenatal diagnosis of sacrococcygeal teratoma in both twins, one patient requested and obtained termination of pregnancy at 19 weeks (Figs. 1 and 2). The remaining four cases were diagnosed at the time of delivery. The maternal serum α-fetoprotein and amniotic fluid α-fetoprotein and acetylcholinesterase had not been tested. There was a 50% (four of eight) prematurity rate. The overall average gestational age was 35.5 ± 4 weeks. There was a 75% (six of eight) cesarean section rate. In the four cases where prenatal diagnosis was made by ultrasound, the presence of a large tumor (average volume 2340 ± 1026 cm^3) affected the mode of delivery. In none of these cases was the infant delivered immediately after the diagnosis was made. In three of them, serial ultrasound examinations were performed and the fetus was delivered abdominally because of an abnormal nonstress test, premature rupture of the membranes, and polyhydramnios, respectively. In the four cases without prenatal diagnosis, two infants were delivered vaginally. The average volume of these tumors was relatively small (average volume 317 ± 197 cm^3). The remaining two infants were delivered by cesarean section for obstetric reasons (transverse lie and failure to progress, respectively, Table I).

Significant morbidity was seen in one case. Because of the large size and vascularity of the tumor, the infant developed hypovolemic shock during the resection operation resulting in subsequent pre-renal failure. Fig. 3 illustrates the size and vascularity of the teratoma. The infant received appropriate management and was normal at follow-up 2 years later.

Fig. 1. Long-axis ultrasound of twin A, showing caudal unilocular cystic mass.

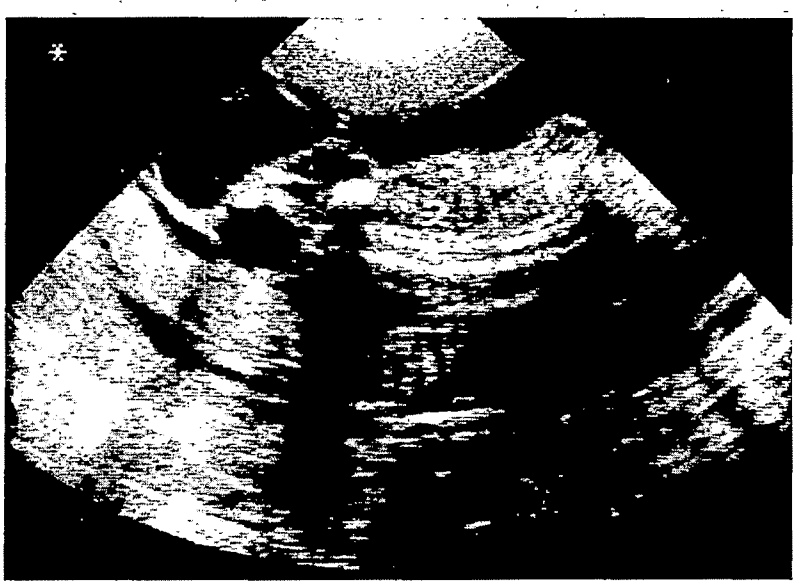

Fig. 2. Long-axis ultrasound of twin B, showing large caudal multilocular cystic mass.

There was one neonatal death secondary to prematurity and one death at 3½ years of age secondary to malignant endodermal sinus tumor, apparently unrelated to the original lesion.

The tumor was resected during the first week of life in surviving neonates and all the tumors were benign. No associated anomalies were found prenatally by ultrasound or at subsequent operation.

Comment

Our series was consistent with some known features of sacrococcygeal teratoma. It is more common in female infants (75% to 80%)[2] and there is concordance between twins.[3] As with many congenital malformations, sacrococcygeal teratoma is associated with polyhydramnios.[4] None of the tumors in our series, however, were malignant. No associated anomalies of the lower vertebrae, anorectum, or genitourinary system were documented.

With respect to prenatal diagnoses, while none of the cases were tested for elevated amniotic fluid α-fetoprotein and acetylcholinesterase levels, these enzymes have been found to be elevated in sacrococcygeal teratoma, especially in the second trimester.[5] Although elevation of these enzymes would not likely have affected the diagnosis in these cases, further study in this area is

10	F	3160	38	38	—	6 by 4 by 5	Vaginal

warranted. As seen in our series, where no ultrasonographic errors were made, careful ultrasonography can be a very accurate method of prenatal diagnosis and assessment. The important differential diagnosis of meningomyelocele and to a lesser extent hemangioma should not be forgotten.

We therefore recommend that, while a rare entity, sacrococcygeal teratoma should be suspected in a large-for-dates patient, and ultrasound examination should be performed in order to make the diagnosis prenatally. These patients should be evaluated by serial ultrasonography to assess tumor size. Appropriate counseling at the time of diagnosis is essential, not only in order to discuss possible termination but also to adequately educate and prepare parents for the impending labor, delivery, and management.

The literature documents different modes of management: (1) vaginal delivery,[3] (2) cesarean section,[4] (3) cesarean section after partial delivery because of dystocia,[6] (4) vaginal drainage of tumor followed by vaginal delivery,[7] and (5) abdominal drainage of tumor followed by vaginal delivery.[8] While mode of delivery has been individualized in the literature, tumor size is critical in this decision for two reasons. In our two cases of vaginal delivery, the tumors were small enough for delivery; however, a large tumor can cause serious obstetric complications such as abnormal lie and dystocia. More importantly, as seen in our one case of hypotensive shock, a large sacrococcygeal teratoma can be highly vascular, thereby causing exsanguination or rupture on aspiration. The literature documents cases of neonatal death after rupture of sacrococcygeal teratoma during vaginal delivery.[9]

On the basis of the above literature review and our own series of cases, we feel it reasonable to suggest that, except for very small tumors (≤5 cm in diameter), cesarean section affords the obstetrician maximal control.

Thus, with prior knowledge, adequate preparation can be made with respect to obstetric management. Appropriate medical and surgical pediatric care can

be obtained with good outcome anticipated in most cases.

We would like to thank Dr. Yung and Dr. Claessens for providing cases for this study.

Human chorionic gonadotropin, prolactin, estriol, and dehydroepiandrosterone sulfate concentrations in cord blood of premature and term newborn infants: Relationship to the sex of the neonate

Basil Ho Yuen, M.B., Ch.B., and Everett K. Mincey, Ph.D.
Vancouver, British Columbia, Canada

Although the composition of human chorionic gonadotropin, prolactin, estriol, and dehydroepiandrosterone sulfate in the umbilical cord blood has been studied, less information is available on the effect of fetal sex on the cord blood concentrations. We assayed these hormones in cord blood from 405 newborn infants delivered between 23 and 43 weeks of gestation. In pooled data for both sexes, human chorionic gonadotropin showed a declining trend from the beginning to the end of the sampling interval. By contrast, in 398 newborn infants of known sex, prolactin, estriol, and dehydroepiandrosterone sulfate levels increased during the same period. Sex differences were observed for human chorionic gonadotropin only; female newborn infants had higher cord blood concentrations throughout the sampling period, with the differences becoming statistically significant between 29 and 36 weeks. (AM J OBSTET GYNECOL 1987; 156:396-400.)

Key words: Newborn infants, sex, chorionic gonadotropin, prolactin, estriol, dehydroepiandrosterone sulfate, cord blood

Human chorionic gonadotropin, prolactin, estriol, and dehydroepiandrosterone sulfate are important polypeptide and steroid hormones produced in the fetal-placental unit. Although their composition in the umbilical cord blood has been studied, less information is available on the effect of fetal sex on the cord blood concentrations.[1, 2] In the present study, we measured the levels of these hormones in the cord blood of newborn infants from midpregnancy to term to determine whether there were any sex differences in these levels.

tetraacetic acid as anticoagulant. Plasma was separated and stored frozen at −25° C until radioimmunoassay of the hormones.[3-5] The prolactin data from 405 newborn infants were reported in relationship to the presence or absence of respiratory distress syndrome together with that of estradiol and thyroid hormones.[6] The development of respiratory distress syndrome did not affect the results of prolactin determinations or the remaining hormone levels reported here. The data were accordingly pooled without regard to the presence

or absence of this disease. Medications of various types were used during pregnancy and labor involving 161 newborn infants. These were isoxsuprine in 68 (42%), glucocorticoids in 21 (13%), and various other agents, singly and in combination in the remaining neonates exposed to medications. In addition, numerous complications of pregnancy, including diabetes mellitus and hypertension, were also encountered, as previously described.[6] Data on the sex of seven newborn infants were not available, leaving a total of 398 infants from whom hormone data were obtained for analysis according to the sex of the infant. Data were analyzed by use of the *t* test.

Results

Data for all newborn infants are shown in Table I and Fig. 1. The data are shown separately for male and female infants in Table II and Fig. 2.

Cord blood levels of human chorionic gonadatropin were 90 ± 28 mIU/ml (mean ± SEM, second international standard) between 23 and 28 weeks of gestation and 95 ± 31 mIU/ml between 29 and 32 weeks; levels declined to 26 ± 4 mIU/ml toward the end of the sampling period at 41 to 43 weeks. Prolactin levels were 81 ± 19 and 261 ± 13 ng/ml; estriol, 119 ± 13 and 208 ± 19 ng/ml; and dehydroepiandrosterone sulfate, 1575 ± 162 and 1961 ± 124 ng/ml, respectively, at the beginning and end of the sampling interval. Sex differences were seen for human chorionic gonadotropin only, with female infants having higher cord blood values throughout the period studied between 23 and 43 weeks of gestation. Concentrations of human chorionic gonadotropin were significantly higher in female infants between 29 and 36 weeks of gestation.

Comment

The data presented indicate that umbilical cord blood concentrations of human chorionic gonadotropin show essentially a declining trend from midpregnancy to term. In contrast, prolactin, estriol, and dehydroepiandrosterone sulfate levels increased during the same interval. Sex differences were observed for human chorionic gonadotropin only. Female infants had significantly higher levels of human chorionic gonadotropin between 29 and 36 weeks of gestation.

For human chorionic gonadotropin, these data are in agreement with those of Boroditsky et al.,[7] Brody and Carlstrom,[8] and Danzer et al.,[9] indicating that circulating maternal levels of human chorionic gonadotropin were higher in women bearing female fetuses compared with women bearing male fetuses. Crosignani et al.[10] reported no sex differences in human chorionic gonadotropin levels of female and male infants between 38 and 41 weeks of gestation in their study. Our data showed higher levels of human chorionic gonadotropin for female infants over male infants throughout the period of 23 to 43 weeks of gestation; however, the data were statistically significant ($p < 0.05$) only between 29 and 36 weeks. In this context, our results are consistent with those of Crosignani et al.[10] inasmuch as neither study observed statistically significant differences in the interval from 37 weeks to term. The higher human chorionic gonadotropin levels in the cord and maternal blood in pregnancy with a female fetus are also associated with higher "female" amniotic fluid levels, compared with "male" amniotic fluid concentrations.[10] Furthermore, Wide and Hobson[11] also found that "female" placental tissue contains more human chorionic gonadotropin than "male" placental tissue. Because umbilical arterial progesterone concentrations are higher in male fetuses, Boroditsky et al.[7] suggested that progesterone may regulate production of human chorionic gonadotropin. In support of this interpretation, Wilson et al.[12] found that progesterone suppressed production of human chorionic gonadotropin from explants of human term placenta.

Weeks of gestation

244 ± 10	247 ± 9	254 ± 21	268 ± 17
(83)	(111)	(21)	(26)
197 ± 12	200 ± 11	238 ± 39	201 ± 26
(52)	(66)	(9)	(16)
1900 ± 109	1904 ± 86	2015 ± 188	1960 ± 174
(52)	(66)	(9)	(16)

In vivo and in vitro observations suggest that prolactin may also inhibit production of human chorionic gonadotropin from trophoblast near term.[13] The temporal relationship between the rising concentrations of prolactin and the declining levels of human chorionic gonadotropin in the fetal compartment (Table I and Fig. 1) is consistent with a possible inhibitory effect of prolactin noted. However, because sex differences for prolactin could not be demonstrated, it seems unlikely that prolactin is playing an important role in the increased human chorionic gonadotropin levels in female fetuses (Table II, Fig. 2).

Our results agree with those of Tapaininen et al.[14] and Badawi et al.[15] in which sex differences for prolactin could not be found. With respect to estriol and dehydroepiandrosterone sulfate, our results are also consistent with those of Laatikainen and Peltonen[16] who found that concentrations of these steroids were not influenced by the sex of the newborn infant.

Human chorionic gonadotropin may have adrenocorticotropic activity before 20 weeks of gestation. In the anencephalic fetus, the adrenal glands develop normally until 20 weeks; thereafter, the adrenal glands start to undergo atrophy in the presence of normal levels of human chorionic gonadotropin and prolactin.[2] The normal development of the adrenal glands of the anencephalic fetus before 20 weeks of gestation may be sustained by the high human chorionic gonadotropin levels produced by the trophoblast in early pregnancy.[2] Atrophy of the anencephalic fetal adrenal glands in later pregnancy in the presence of normal human chorionic gonadotropin and prolactin levels is consistent with adrenocorticotropic hormone being the major hormone after midpregnancy.[2] Fetal pituitary prolactin content is low before 15 weeks of gestational age but increases rapidly from this period to 23 weeks. Prolactin has also been proposed as a possible adrenocorticotropic hormone in the fetus.[2] The observation of normal prolactin levels in the anencephalic fetus with atrophic adrenal glands suggests that it is unlikely that prolactin has an important adrenocorticotropic role in utero.[2] The major secretory product of the fetal adrenal gland is dehydroepiandrosterone sulfate, which is the precursor of estriol in the fetal-placental unit. Glucocorticoids administered to the mother inhibit adrenocorticotropic hormone secretion with a decrease in the production of dehydroepiandrosterone sulfate and estriol. Although we do not know the effect of the various maternal complications of pregnancy or of the drugs used during pregnancy and labor on the hormone results reported here, our data appear to confirm and extend previous observations.

In conclusion, mean cord blood human chorionic gonadotropin concentrations from pooled data of both male and female newborn infants show a declining trend from 23 weeks of gestation to term. In contrast, mean cord blood levels of prolactin, estriol and dehydroepiandrosterone sulfate show an increasing trend during the same interval of pregnancy. Sex differences were observed for human chorionic gonadotropin only. The mean concentrations of human chorionic gonadotropin in the cord plasma of female newborn infants exceeded that of male newborn infants between 23 and 43 weeks of gestation; between 29 and 36 weeks of gestation, this difference was statistically significant.

Differing concentrations of human chorionic gonadotropin and prolactin in the cyst fluid of hydatidiform mole and in amniotic fluid

Basil Ho Yuen, M.B., Ch.B.
Vancouver, British Columbia, Canada

The concentrations of human chorionic gonadotropin and prolactin in the cyst fluid of molar tissue were compared with that of normal amniotic fluid. Molar fluid was aspirated from the vesicles of molar tissue in eight women (duration of amenorrhea 14.1 ± 1 week, mean ± SEM). Amniotic fluid was obtained at amniocentesis in 24 women (mean duration of amenorrhea 15.9 ± 0.2 week). Hormones were measured by specific radioimmunoassay. The concentrations (mean ± SEM) of human chorionic gonadotropin in molar fluid and amniotic fluid were 581,829 ± 112,581 and 3187 ± 505 mIU/ml ($p < 0.001$), respectively. For prolactin the levels in molar fluid and amniotic fluid were 44 ± 24 and 1962 ± 313 ng/ml ($p < 0.001$), respectively. These data demonstrate that molar fluid contains 182-fold higher levels of human chorionic gonadotropin and 45-fold lower levels of prolactin than amniotic fluid obtained from normal pregnant women with a similar duration of amenorrhea. In addition to altered endocrine function of the trophoblast, there may be altered prolactin secretion from the decidua in molar pregnancy as compared with normal pregnancy. Further research is required to evaluate prolactin production from decidua of molar pregnancy. (AM J OBSTET GYNECOL 1987;156:400-2.)

Key words: Human chorionic gonadotropin, prolactin, molar cyst fluid

During normal pregnancy human chorionic gonadotropin levels in amniotic fluid are lower than those in the maternal blood.[1] Prolactin levels in amniotic fluid rise as gestation progresses to peak in the midtrimester and then decline toward term.[1,2] The source of human chorionic gonadotropin in normal and molar pregnancy is the trophoblast.[3] The source of prolactin in the amniotic fluid has not been clearly defined. Recent studies[4,5] demonstrate that the decidua secretes prolactin and that the mechanisms controlling its secretion from this tissue differs from that of the pituitary gland.[6] It has been suggested that the decidua is an important source of amniotic fluid prolactin.[4,5] The physiologic role of prolactin in amniotic fluid has not been defined. It has been suggested, however, that prolactin may have an osmoregulatory role in the formation of amniotic fluid.[1,4] The concentrations of prolactin in molar vesicular fluid have not previously been determined.

Table I. β-Subunit of human chorionic gonadotropin and prolactin concentrations in amniotic fluid and molar cyst fluid

	Amniotic fluid (n = 24 women)	*Molar cyst fluid (n = 8 women)*	*p*
β-Subunit of human chorionic gonadotropin* (mIU/ml)	3,187 ± 505	580,829 ± 102,581	<0.001
Prolactin (ng/ml)	1,962 ± 313	44 ± 24	<0.001

Data are shown as mean ± SEM.
*Second international standard.

The purpose of the present study was to determine whether the concentrations of these peptide hormones in the amniotic fluid of normal pregnancy differed from those of molar pregnancy at approximately comparable intervals of gestation.

Material and methods

Amniotic fluid was obtained at the time of amniocentesis from 24 women for indications based on maternal age. The women were 36.2 ± 0.5 years of age (mean ± SEM). The duration of amenorrhea at the time of amniocentesis was 15.9 ± 0.2 weeks. Only patients whose amniotic fluid karyotype findings were normal were included in the study. In addition, amniotic fluid samples contaminated with blood or meconium were discarded. Molar cyst fluid was aspirated from the vesicles in the operating room immediately after surgical evacuation of the uterus with the patient under general anesthesia. Only samples that were free of contamination by blood were used. The mean age of the eight women with molar pregnancy was 25 ± 2.5 years and the duration of amenorrhea at the time of evacuation was 14.6 ± 1 week. The amniotic fluid and molar cyst fluid specimens were centrifuged before being stored frozen at −20° C before the hormones were measured by radioimmunoassay. Assay kits for the assay of the β-subunit of human chorionic gonadotropin were purchased from Amersham Canada Limited, Oakville, Ontario, Canada, and prolactin assay kits were purchased from Becton Dickinson Immunodiagnostics, Mississauga, Ontario, Canada. The between-assay coefficient of variation for assay of the β-subunit of human chorionic gonadotropin was 10% while the within-assay coefficient of variation was 8%. For the prolactin assay the between- and within-assay coefficients of variation were 11% and 5%, respectively. Data were analyzed by the Mann-Whitney test.

Results

The duration of amenorrhea in women with normal pregnancy at the time of amniocentesis was not significantly different from that of the women with molar pregnancy at the time of uterine evacuation. However, the women undergoing amniocentesis were significantly older ($p < 0.05$) than the women with evacuation of a molar pregnancy.

Hormone results are shown in Table I.

Comment

The human chorionic gonadotropin and prolactin concentrations of amniotic fluid reported are in agreement with those of other authors.[1-3] The mean human chorionic gonadotropin level in amniotic fluid was 3187 mIU/ml while in molar cyst fluid the mean human chorionic gonadotropin level was 580,829 mIU/ml. The mean prolactin levels in amniotic fluid and molar cyst fluid were 1962 and 44 ng/ml, respectively.

In the present study the human chorionic gonadotropin levels in the molar cyst fluid were about 180-fold higher than those of normal amniotic fluid for the same stage of amenorrhea. In contrast, the prolactin levels in molar cyst fluid were 45-fold lower than those of amniotic fluid for similar stages of amenorrhea. These findings suggest that, in addition to the altered endocrine function of the trophoblast, there is altered prolactin secretion within molar pregnancy as compared with that in the fetal-placental compartment of normal pregnancy. Unlike amniotic fluid, the molar cyst fluid is characterized by high human chorionic gonadotropin and low prolactin concentrations. Since trophoblast is the major source of human chorionic gonadotropin secretion, the higher human chorionic gonadotropin levels in molar cyst fluid reflect the excess production of human chorionic gonadotropin by molar trophoblast. As compared with normal placental tissue of comparable duration of pregnancy, hydatidiform mole tissue has been shown to have a higher human chorionic gonadotropin content.[3] Although the reasons for the lower prolactin levels in molar pregnancy cyst fluid are not known, they may include altered production from the decidua. Should this be so, the decidua of molar pregnancy may share a feature with decidua of spontaneously aborting embryopathic pregnancy, where the production of prolactin appears to be somewhat less than that of normal pregnancy.[7] As previously noted, in normal pregnancy, the decidua may

be an important source of amniotic fluid prolactin.[4, 5] Further research is required to determine if prolactin production from the decidua of molar pregnancy is altered. Other possible explanations for the observations presented may include mechanisms representing an altered net clearance of prolactin and human chorionic gonadotropin from the trophoblast-decidua complex of molar pregnancy as compared with that of the normal fetal-placental unit. Furthermore, the role of the fetus in the distribution of these hormones in the normal fetal-placental unit has not been elucidated.

In conclusion, the vesicular fluid of molar pregnancy, as compared with that of normal amniotic fluid, contains a great deal more human chorionic gonadotropin but much less prolactin. In addition to altered endocrine function of trophoblast in molar pregnancy,[3] prolactin secretion from the decidua may also be altered. Further research is required to evaluate prolactin production from decidua of molar pregnancy.

I thank Dr. L. Kirby for samples of amniotic fluid.

Doppler ultrasound prediction of fetal outcome in twin pregnancies

C. Nimrod, M.B., D. Davies, R.D.M.S., J. Harder, M.D., C. Dempster, R.D.M.S., G. Dodd, R.N., N. McDicken, Ph.D., and S. Nicholson, M.D.
Calgary, Alberta, Canada

The usefulness of pulsed Doppler ultrasound in predicting twin pregnancies destined for unsatisfactory outcomes was examined in 30 twin pregnancies. Fetal flow velocity waveform analysis (systolic/diastolic ratio and pulsatility index) and quantitative analysis in the descending aorta and umbilical artery demonstrated good sensitivity and specificity when compared with biparietal diameter and abdominal circumference measurements. This technique shows some promise as a useful adjunct in the management of twin pregnancies. (Am J Obstet Gynecol 1987;156:402-6.)

Key words: Twin pregnancies, outcome, pulsed Doppler ultrasound

Twin gestation is associated with a significant increase in perinatal morbidity and mortality. This increase is mainly attributed to premature delivery and growth discrepancy.[1] Ultrasound is a useful tool in the assessment of growth problems; however, the sensitivity of biparietal diameter differences of >7 mm in the same twin gestation in predicting growth failure has been reported at only 20%.[2] This limitation has emphasized the need for a better diagnostic test to identify pregnancies at risk for compromise. The usefulness of flow velocity waveform analysis in the assessment of fetal health has been addressed previously.[3] Increased vascular impedance downstream from the point of Dopp-

ler sampling will cause decreased diastolic flow, which will result in changes in both the peak systolic/end diastolic ratio and the $\frac{\text{peak systolic–end diastolic}}{\text{mean flow}}$ ratio, that is, the pulsatility index.[4] This study prospectively evaluated the changes occurring in blood flow in twin gestations and assessed the value of these measurements in predicting pregnancies destined to produce unsatisfactory outcomes.

Material and methods

Consecutive patients who presented to the ultrasound department with twin pregnancies beyond 20 weeks' gestation were recruited into this study. Fetal Doppler ultrasound research was approved for study in our institution. Routine biometric parameters including biparietal diameter and abdominal circumference were measured according to the methods reported by Hadlock et al.[5,6] Pulsed Doppler evaluation of the descending aorta and umbilical artery of each twin was conducted during periods of absent fetal breathing with the use of a Toshiba SAL 50A (Toshiba America, Tustin, California) with a 2.42 MHz pulsed Doppler transducer attached to a 3.5 MHz linear array transducer at a fixed angle of 55 degrees. A 100 Hz thump filter was used. The system was calibrated by the method of McDicken[7] to ensure that the quantitative estimate of flow was accurate. Patients were either in a supine position or at a slight left lateral tilt during these studies. The fetal descending thoracic aorta was examined just above the level of the diaphragm with the aorta oriented parallel to the transducer. A large enough sample volume was chosen to completely cross the vessel but not provide interference from other vessels. The aortic diameter and Doppler angle were then measured and entered into the machine to allow online calculation of mean velocity and volume flow. The umbilical artery was examined with the position of the sample volume adjusted to provide the best signal. No corrections were made for the Doppler angle and vessel diameter. Freeze-frame images of aortic and umbilical flow velocity waveforms were then used for off-line analysis on a microcomputer with a digitizing pad (Microsonics, Indianapolis, Indiana). Peak systolic and end diastolic velocities were marked by hand for measurement as these end points were clearly visible. Three consecutive waveforms were measured and a simple average calculated. The percent differences between the twin pairs was calculated for each parameter except biparietal diameter, for which millimeter differences were calculated in order to allow for comparison with previous reports.[2]

Pregnancy outcome was correlated with the results of the last ultrasound examination before delivery. Any of the following was considered an unsatisfactory outcome: (1) preterm delivery before 32 weeks' gestation, (2) major birth weight discrepancy of >500 gm, (3) birth weight below the tenth percentile for gestational age,[8] or (4) admission to the neonatal intensive care unit for problems originating in the antenatal period. The Doppler ultrasound information was blinded to the clinicians managing the patients.

Results

Thirty patients were recruited into the study and 11 of these were classified as having an adverse outcome (Table I) (<32 weeks' gestation at delivery, two; below tenth percentile, nine; weight discrepancy >500 gm, six; admission to neonatal intensive care unit, seven). The mean gestational age at the time of the examination was 31.7 weeks for the normal group and 31.8 weeks for the abnormal pairs with the mean gestation at delivery being 37.0 and 34.5 weeks, respectively, for the normal and abnormal groups. There was a statistically significant difference in the mean birth weights between the normal (2560 ± 357 gm) and the abnormal (1810 ± 796 gm) twin pairs ($p < 0.002$). Five infants from the abnormal group died in the perinatal period, while there were no losses in the group classified as normal. Also no significant congenital abnormality was identified in the entire study population. The in vitro calibration of the Doppler system demonstrated

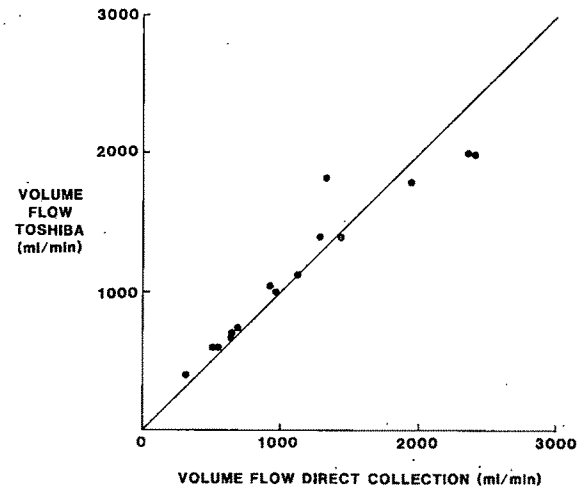

Fig. 1. In vitro calibration of Toshiba Doppler system at different volume flows.

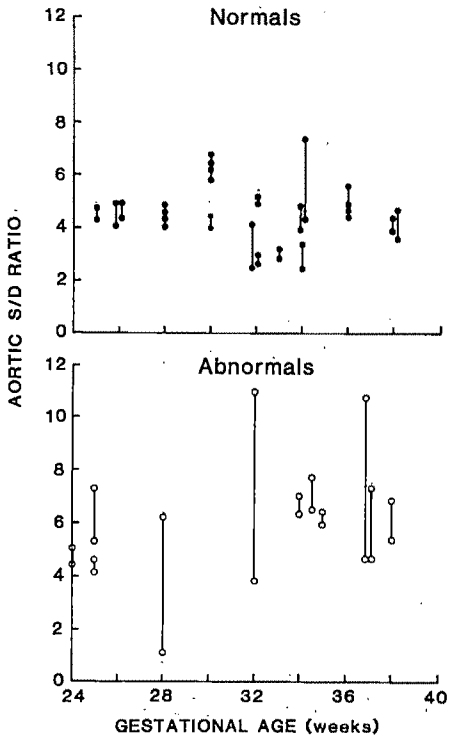

Fig. 2. Aortic peak systolic/end diastolic *(S/D)* ratio at different gestational ages in normal and abnormal twin pairs.

a systematic error of 5% in quantitative flow over a wide range of velocities (Fig. 1).

In two patients, both abdominal circumference and Doppler study of the fetal aorta could not be obtained. The umbilical peak systolic/end diastolic ratio was unobtainable in five different patients classified in the abnormal group and in six patients with normal outcomes. This was due in large part to the difficulty in

identifying which fetus belonged to the cord sampled.

The normal and abnormal twin pair data for aortic peak systolic/end diastolic (Fig. 2), aortic pulsatility index (Fig. 3), and aortic volume flow (Fig. 4) are plotted against gestational age to highlight the differences seen in the individual twin pairs. When abnormal twin pairs are examined, aortic peak systolic/end diastolic ratios accentuate the differences to a greater extent than the pulsatility index. Significant differences are also demonstrated in aortic blood flow volume in the abnormal group after 32 weeks' gestation. The mean percent difference for each parameter in normal and abnormal twin pairs is shown in Table II in conjunction with the standard deviations. In addition, the sensitivity and specificity for a biparietal diameter difference of ≥7 mm and abdominal circumference and Doppler parameters with differences of 1 SD above the mean are shown.

Comment

The umbilical artery has been the vessel most commonly assessed by Doppler ultrasound. This, however, does present a problem in twin gestation as it is not always easy to clarify which fetus is associated with the umbilical vessel under study. Studies on the descending aorta have been shown to be useful;[9] however, the volume flow calculation has had limited use because of the size of the error involved in the assessment of the cross-sectional area of a vessel.[10] The observation that volume flow differences in abnormal fetuses were exaggerated beyond 32 weeks' gestation is understandable in light of the dependence of volume flow on vessel diameter as a reflection of fetal size[11] and the acceleration of fetal growth that occurs around this gestational age.

The only report of Doppler evaluation of twin gestation used umbilical peak systolic/end diastolic ratios.[12] In this study, we attempted to expand this to include waveform analysis and volume flow in the fetal aorta and used a pulsed Doppler system rather than continuous wave. In addition, a new outcome category to include adverse fetal outcome without significant weight discrepancy was used.

This study compares the twins in the form of percent difference. This approach has some limitations as abnormal situations can be masked if both twins are similarly compromised and hence, would have relatively similar blood flow changes. This did not occur in any of our cases but underlines the need to compare the absolute Doppler measurements to the normal range in all cases. For abdominal circumference four of nine patients in the abnormal group had a value below the tenth percentile for our laboratory, but in only two was a significant difference between pairs noted.

In our study, a biparietal diameter difference of >7 mm was equivalent to 1 SD from the mean, and although the sensitivity of 45% is better than the sensitivity of 20% reported by Leveno et al.,[2] it is still too low to be useful as a screening test for predicting unsatisfactory outcome. It does, however, have a low false positive rate of 16%. Abdominal circumference difference was not of value although absolute values were somewhat better. When considered individually, the Doppler parameters all have similar specificities but the sensitivity of the mean velocity and systolic peak velocity was too low to be useful. End diastolic flow and volume flow appear more sensitive than the remaining parameters but are still too low to be useful screening tests on their own. Pulsatility index generated values similar to the peak systolic/end diastolic ratio and was probably testing a similar physiologic parameter. It is unlikely that it would provide more information about the state of the fetal circulation.

Combining parameters has been used effectively for detecting intrauterine growth retardation and forms the basis of well-accepted indices such as the biophysical profile and Apgar score. When biparietal diameter, peak end diastolic velocity, volume flow, and aortic and

umbilical peak systolic/end diastolic are considered together, nine of 11 in the abnormal group had two or more of these parameters outside the normal range, and in the other two cases one or more of the Doppler parameters could not be obtained. This combination of parameters improves the sensitivity to 82%. The specificity, however, is lowered as the false positive rate goes up to 30%. Measurement of several parameters also helps to overcome the technical difficulties encountered in obtaining good Doppler studies in both twins. In all cases, either the umbilical artery or the aorta could be satisfactorily assessed.

In conclusion, Doppler evaluation of fetal vessels is simple and noninvasive and can be performed by skilled sonographers usually in less than 30 minutes. It shows promise as a useful discriminator of birth weight differences and poor outcome in twin pregnancies. Use of several parameters appears to increase the sensitivity even though quantitative analysis (volume flow) may be difficult. Flow velocity waveform analysis should therefore be considered in the management of twin pregnancies.

Congenital and nosocomial sepsis in infants born in a regional perinatal unit: Cause, outcome, and white blood cell response

Arne Ohlsson, M.D., and Mary Vearncombe, M.D.
Toronto, Ontario, Canada

The incidence, cause, and outcome of sepsis and the white blood cell response were studied in 6315 infants born in a regional perinatal unit. The incidence of neonatal sepsis was 6.5 per 1000 live births. Congenital sepsis (12 cases) was overwhelming, with associated maternal infection (92%), neutropenia (75%), and high rate of mortality (50%). The most common organism was *Escherichia coli* (58%). Gestational age and birth weight were similar in survivors and nonsurvivors. There was a strong correlation between total white blood cell count and both mature and immature neutrophil counts in survivors but this correlation decreased substantially in neonates that died. Analysis of variance indicated that the means for polymorphonuclear leukocyte and immature neutrophil counts were significantly higher in survivors. Nosocomial sepsis (38 cases) occurred in premature low birth weight infants receiving invasive, intensive care. The most common organism was *Staphylococcus epidermidis* (76%). Total white blood cell, polymorphonuclear leukocyte, and immature neutrophil counts rose significantly in response to sepsis. None died. Prevention of congenital sepsis requires methods to detect early maternal-fetal infection. Providing granulocytes to neutropenic neonates with congenital sepsis might improve outcome. (AM J OBSTET GYNECOL 1987;156:407-13.)

Key words: Sepsis, congenital, nosocomial, neonate, infant, neutropenia, etiology, outcome

Sepsis is a generalized symptomatic infection confirmed by a positive blood culture. The incidence of sepsis occurring in the neonatal period (<28 days of age) varies from one to 10 per 1000 live births, and the mortality varies from 20% to 75%.[1,2] The handicap rate among survivors exceeds 25%.[2] The susceptibility to and outcome of sepsis relate to the type and number of invading organisms, the gestational age and weight of the neonate, the age at the onset of sepsis, the presence of malformations requiring operation, predisposing maternal conditions, and early diagnosis and therapy.[3,4] If neutropenia develops in a neonate with bacterial sepsis and a bone marrow aspirate demonstrates depletion of the neutrophil storage pool, the likelihood of survival is <20%.[5] Extensive reviews of the literature between 1927 and 1978 have shown that the cause of neonatal sepsis varies with geographic area and with time.[3,6] It is therefore important to frequently review the cause of neonatal sepsis locally.[3,4] The most commonly isolated organisms are *Escherichia coli*, other gram-negative organisms such as *Klebsiella, Enterobacter,* and *Serratia marcescens,* group B streptococci, and *Staphylococcus aureus.*[3,6] Recently an increasing incidence of nosocomial sepsis caused by *Staphylococcus epidermidis*[7-9] and *Candida albicans*[10,11] has been noted in neonatal intensive care units.

The purpose of this study was to determine the incidence, cause, and outcome of sepsis occurring among infants recently born in a regional perinatal unit. The white blood cell response to sepsis in these infants was also studied to establish the number of infants that might benefit from granulocyte transfusion.

Material and methods

Population studied. All infants with both clinical signs of sepsis and a positive blood culture, born in the University of Toronto Regional Perinatal Unit at Women's College Hospital, Toronto, Ontario, Canada, during 1984 and 1985, were studied.

Culture procedures. Blood cultures were obtained either from the umbilical artery at the time of the initial catherization at birth or from a peripheral vein after thorough preparation of the skin with iodine solution. Before September 1984, blood cultures were inoculated into a radiometric hypertonic aerobic medium (Bactec 8A, Johnston Laboratories) and incubated at 35° C for 7 days. From September 1984 to the end of the study period, blood for cultures was inoculated into pediatric Isolator tubes (DuPont) and plated onto chocolate agar and Brucella agar plates according to the manufacturer's instructions. Plates were incubated in 5% carbon dioxide and anaerobically, respectively, at 35° C for 4

days. Growth was quantitated as the number of colonies per milliliter of blood. In all cases of suspected sepsis cerebrospinal fluid was obtained for cell count, Gram stain, and culture. Appropriate cultures and Gram stains were performed on material from any focal infection. Central indwelling venous catheters were not used during the study period, but when nosocomial infection was suspected any peripheral vascular line was removed and cultured by a semiquantitative technique.[12]

Maternal risk factors. The following maternal risk factors known to be associated with neonatal sepsis were noted: infection, time between rupture of the membranes and delivery, and antenatal treatment with antibiotics and/or steroids. Maternal hospital stay before delivery was recorded in congenital sepsis. During the study period, unless contraindicated, all mothers in premature labor at 25 to 32 weeks' gestation were given Vasodilan (Mead Johnson & Co.) in an attempt to stop labor to allow time for the action of bethamethasone. They were given two 12 mg doses of betamethasone 12 hours apart to promote fetal lung maturation. If labor recurred after the bethamethasone effect had been established no attempt was made to stop labor in the presence of premature rupture of the membranes.

Mothers presenting with premature rupture of the membranes had an introital swab taken for culture for group B streptococci. They were then given one million units of penicillin G every 6 hours intravenously until results of cultures were available. The treatment was stopped if the cultures were negative and continued if positive until two consecutive cultures were negative. If an introital swab was positive for group B streptococci at any time during the pregnancy, treatment with penicillin was given during labor. Erythromycin was used instead of penicillin in case of penicillin allergy.

Blood work and criteria. Peripheral total white blood cell counts, polymorphonuclear leukocyte counts, and immature neutrophil counts were obtained in all infants at the time of suspected sepsis. In nosocomial sepsis these results were compared to results of tests that had been performed within the two preceding days. Granulocytopenia was defined according to the criteria established by Xanthou[13] as <1300 polymorphonuclear leukocytes per cubic millimeter. The immature/total neutrophil ratio was calculated according to Manroe et al.[14] Bone marrow aspiration to evaluate the neutrophil storage pool was not performed.

Treatment. All infants were given full life support as indicated. Ampicillin and gentamicin in combination were used initially in the treatment of suspected sepsis and the antibiotics were subsequently changed according to sensitivity of the bacterial isolates.

Statistical analysis. Statistical analysis comparing groups was performed with the use of a paired two-tailed Student's *t* test on the leukocyte response to nosocomial sepsis. In congenital sepsis a two-factor analysis of variance with repeated measures was used on the polymorphonuclear and immature neutrophil counts at birth and 24 hours after birth. Some correlation matrices were obtained on the above sets of data. These statistical procedures were carried out after a square root transformation.

Results

During the 2-year study period there were 6315 live births, and septicemia was diagnosed on 50 occasions (54 bacterial isolates) in 49 patients at age 0 to 79 days. Neonatal sepsis occurred on 41 occasions, an incidence of 6.5 per 1000 live births. Sepsis occurred on nine occasions in infants older than 28 days of age. Concomitant meningitis occurred in one infant with *E. coli* sepsis. None of the patients had a major congenital malformation, and none underwent operation. The overall mortality was 12%. Two distinct groups of septic infants could be identified.

Congenital sepsis. In group 1 (12 neonates) sepsis was congenital (Table I). The male/female ratio was 1/1. The mortality was 50% and neutropenia was common (75%). The immature/total neutrophil ratio was increased (>0.16) in 75% of neonates with congenital sepsis. All neonates that died were neutropenic and had an immature/total neutrophil ratio that varied between 0.1 and 0.9. Eleven of the twelve (92%) mothers who gave birth to a neonate with congenital infection also showed signs of infection (Table I). Eight had premature rupture of the membranes >12 hours (67%); eight (67%) were treated with steroids and six (50%) with penicillin before delivery. Eight mothers (67%) had been in the hospital >12 hours and seven (58%) >24 hours before delivery. There was no significant difference in gestation age or birth weight between survivors and nonsurvivors with congenital sepsis. *E. coli* was the most common organism isolated (58%). All bacteria causing congenital sepsis were sensitive to at least one of the routinely used antibiotics (ampicillin and gentamicin). The mortality rate was 50%.

Table III. White blood cell counts (mean ± SD) in survivors and nonsurvivors of congenital sepsis at birth and at 24 hours of age

	Nonsurvivors	*Survivors*
Day of birth		
No.	6	6
Total white blood cell count (No./mm³)	7,583 ± 6,585	18,300 ± 13,843
Polymorphonuclear leukocytes (No./mm³)	630 ± 454	6,587 ± 12,014
Immature neutrophils (No./mm³)	1,427 ± 2,464	4,301 ± 4,249
Second day of life		
No.	4	6
Total white blood cell count (No./mm³)	2,900 ± 1,042	19,650 ± 8,996
Polymorphonuclear leukocytes (No./mm³)	413 ± 577	8,496 ± 4,467
Immature neutrophils (No./mm³)	805 ± 693	5,190 ± 9,425

Nosocomial sepsis. In group 2 sepsis was nosocomial (37 infants with 38 septic episodes) with onset between 7 and 79 days (Table II). The clinical and laboratory findings were similar in late-onset neonatal sepsis and in sepsis occurring in infants older than 28 days. There were no episodes of sepsis diagnosed between 1 and 6 days of age. Therefore, all infants with sepsis presenting after birth were grouped and analyzed together as nosocomial sepsis. The male/female ratio was 1.7/1. There was no significant difference in mean gestational age between male (28.4 ± 2.2 weeks) and female (27 ± 2.6 weeks) infants, but male infants had a significantly higher mean birth weight (1145 ± 282 gm) compared with that of female infants (866 ± 196 gm) ($p < 0.005$).

There were no deaths in infants with nosocomial sepsis and neutropenia was always absent at the time of diagnosis. Sixty percent of the infants had an elevated immature/total neutrophil ratio (>0.12). Seventy-six percent of nosocomial bacterial isolates were *S. epidermidis* followed by *E. coli* (12%) and *Enterobacter cloacae* (7%). Sixty-three percent (20 of 32) of *S. epidermidis* isolates were resistant to methicillin. Bacterial isolates other than *S. epidermidis* were sensitive to either ampicillin or gentamicin. Twenty-four of the 37 mothers (65%) had been treated with steroids before delivery and 11 (30%) with antibiotics. Nine mothers (24%) had premature rupture of the membranes for >12 hours. There were no deaths.

White blood cell response. The white blood cell responses to congenital sepsis and nosocomial sepsis are presented in Tables III and IV. Three neonates with congenital sepsis (25%) and seven with nosocomial sepsis (18%) had a platelet count <150,000/mm³ at the time of diagnosis. Correlation matrices between total white blood cell counts, polymorphonuclear leukocyte counts, and immature neutrophil counts in survivors and nonsurvivors of congenital sepsis are presented in Table V and the same correlation matrices for nosocomial sepsis 2 days before diagnosis and on the day of diagnosis are presented in Table VI. The cell means for the model used in analysis of variance for white blood cell count at birth and 24 hours after birth in congenital sepsis are shown in Table VIIA, with the corresponding analysis of variance shown in Table VIIB.

Comment

The incidence of sepsis in this study corresponds to those of earlier recent reports.[1-4, 6] Multiple risk factors were present in mothers of neonates with congenital sepsis: maternal infection, premature rupture of the membranes, and antenatal treatment with steroids and antibiotics. Nine mothers had been in the hospital for more than 12 hours and seven for more than 24 hours but the maternal-fetal infection was either not suspected or suspected only at parturition in most cases. Antenatal maternal treatment with steroids may have contributed to the seriousness of the infection in the neonate. Presently the methods to detect maternal infection are crude and the most sensitive test, C-reactive protein, has a high sensitivity but a low specificity.[15] Innovative approaches to this maternal population could possibly modify the very high mortality and survivor morbidity of congenital sepsis. In our population congenital sepsis was caused either by virulent bacteria with capsular polysaccharide antigens or in one patient by *Candida albicans*. *E. coli* was the major pathogen, as shown in other reviews of the cause of neonatal sepsis.[3, 6] Group B streptococci were of minor importance in this study compared with its role described in the literature.[3, 6] This might be explained by the routine use of penicillin in mothers with premature rupture of the membranes, which could have selected other penicillin-resistant organisms. *Streptococcus pneumoniae, Haemophilus influenzae* type b, and *C. albicans*, each isolated once, rarely cause congenital sepsis.[3, 4] All bacteria causing congenital sepsis were sensitive to at least one of the two antibiotics that are routinely used in the initial treatment of suspected sepsis in our unit. Ampicillin and gentamicin in combination should therefore remain the antibiotics of choice in the treatment of congenital sepsis.

The importance of *S. epidermidis* as a cause of nosocomial sepsis was shown in this study. Gram-negative nosocomial sepsis was rare in our unit and our results differ considerably from those of a study by Whyte et al.[8] from the neonatal unit at the Hospital for Sick Children, Toronto. They studied nosocomial infections

Table IV. White blood cell count response (mean ± SD) in nosocomial sepsis

	Within 2 days before diagnosis	*On day of diagnosis*	*Significance*
Total white blood cell count (No./mm³)	15,588 ± 7,157	27,163 ± 13,738	$p < 0.0000004$

in infants born at <32 weeks' gestation and weighing <1250 gm, who were admitted from the same catchment area as the mothers in our unit. In their study the most commonly isolated bacteria in nosocomial sepsis (33 infants) were *S. epidermidis* (24%), *Klebsiella pneumoniae* (24%), and *E. coli* (21%). Although the catchment area is the same, the populations differ in that at Women's College Hospital all infants are delivered in the unit, whereas the neonatal unit at the Hospital for Sick Children treats only referred patients, including a large number of patients with disorders requiring operation. Continuing surveillance of the bacterial flora in each neonatal unit is therefore important to ensure appropriate therapy.

S. epidermidis sepsis occurs in infants receiving intensive, invasive care including respiratory support and hyperalimentation. An intravenous infusion site is, in our experience, as well as in the experience of others,[9] the usual source of entry (Table II).

Two of our infants, who had no obviously infected infusion site, had growth of the same strain of *S. epidermidis* in their endotracheal tubes. The trachea could possibly be another site of entry when an endotracheal tube requiring frequent manipulation is present. A large percentage (63%) of *S. epidermidis* isolates were resistant to methicillin but all were sensitive to vancomycin. It is important for both diagnosis and therapy that any indwelling infusion line is removed as soon as sepsis is suspected. Treatment with vancomycin should be initiated when significant *S. epidermidis* bacteremia is a likely cause of sepsis in the clinical situation.[9]

The overall mortality was low (12%) compared with that of other studies.[1,2] The mortality in congenital sepsis was 50%, which compares with 42%,[4] 69%,[8] and 70%[7] in three recent studies. In contrast there was no mortality in nosocomial sepsis, which has a reported mortality of 12%,[7] 20%,[4] and 39%.[8]

It is well known that congenital sepsis is often associated with neutropenia, and this association carries a poor prognosis.[4,5,7] This was confirmed in our study, as death occurred only in neutropenic infants.

Christensen et al.[5] found that neonates with an immature/total neutrophil ratio in excess of 0.8 are likely to have critical diminution of marrow neutrophil re-

Table VIIA. Polymorphonuclear leukocyte and immature neutrophil count means, after square root transformation, at birth, and 24 hours later

State	*At birth*		*24 hr later*	
	Polymorphonuclear leukocyte count	*Immature neutrophil count*	*Polymorphonuclear leukocyte count*	*Immature neutrophil count*

Time (birth/24 hr)	1	242.43708	0.23	0.6444
Cell type*	1	1023.40869	0.42	0.5342
Time · cell type	1	436.17562	1.01	0.3453

*Polymorphonuclear leukocyte count/immature neutrophil count.

serves, which can be confirmed by a marrow aspirate. In our study only four neonates (two died and two survived) had an immature/total neutrophil ratio >0.8 at birth or at 24 hours of age. In congenital sepsis there was a high correlation between total white blood cell counts and both polymorphonuclear leukocyte counts and immature neutrophil counts in survivors, but this correlation decreased substantially in neonates that died (Table V), indicating that these neonates were not able to mount a neutrophil cell response to sepsis. As seen in Table VIIB the main effect of state (dead-alive) was the only significant result ($p < 0.0081$). Thus analysis of variance confirmed that the groups that survived and died of congenital sepsis differed in regard to polymorphonuclear leukocyte counts and immature neutrophil counts. The means for polymorphonuclear leukocyte counts and immature neutrophil counts across the living group were substantially higher than the means in the group that died. Short of marrow aspiration, an excellent predictor of outcome in congenital sepsis in our population was neutropenia at birth that persisted at 24 hours of age. Three of six survivors with congenital sepsis were neutropenic at birth but had a normal mature neutrophil count at 24 hours of age. In contrast all six infants that died were neutropenic at birth and by 24 hours they either had died (two) or were still neutropenic and would eventually die (four).

Infants with nosocomial sepsis were not neutropenic at the time of diagnosis but showed a highly significant rise in total white blood cell counts, polymorphonuclear leukocyte counts, and immature neutrophil counts compared with counts within 2 days before diagnosis (Table IV). In Table VI it is worth noting that the correlation between polymorphonuclear leukocyte counts and immature neutrophil counts changed direction between the two matrices, from −0.3220 in matrix 1 to 0.3250 in matrix 2. Also there was a substantial increase in the correlation between immature neutrophil counts and total white blood cell counts; the correlation increased from 0.0282 to 0.6311. In the neonates with nosocomial infection in this study, a marked increase in total white blood cell counts, polymorphonuclear leukocyte counts, and immature neutrophil counts thus occurred. In contrast this response was lacking in neonates that died of congenital infection.

This review shows that the causes of congenital sepsis differ between populations. In nosocomial sepsis the cause also differed from that found in another unit in the same city, even though the mothers-infants were recruited from the same catchment area. The present treatment of congenital sepsis in our unit with ampicillin and gentamicin is adequate in view of bacterial causes. As death occurred only in congenital sepsis, in spite of appropriate antibiotics, efforts to improve outcome should concentrate on prevention and innovative therapies. Methods to improve early detection of maternal-fetal infection are essential. This study identified a small number of neutropenic neonates with sepsis who may benefit from a treatment that would increase the number of mature granulocytes, by either exchange transfusion with fresh blood or granulocyte transfusion.[16] As these neonates are critically ill at birth and deteriorate rapidly, it is essential that all diagnostic tests and treatment modalities are readily available on a 24-hour basis in spite of the rare occurrence of neonates that would qualify for the treatment. It is also important that neonates subjected to any new type of treatment have long-term follow-up for evaluation of the ultimate effect of the treatment on perinatal morbidity and biologic-psychological-social handicaps.

Postmenopausal estrogen and androgen replacement and lipoprotein lipid concentrations

Barbara B. Sherwin, Ph.D., Morrie M. Gelfand, M.D., Reuben Schucher, Ph.D., and Joseph Gabor, M.Sc.

Montreal, Quebec, Canada

The effect of a combined estrogen-androgen drug on the lipoprotein lipid profile of women who received it parenterally as long-term postmenopausal replacement therapy was compared to that of women who had been receiving estrogen alone parenterally and to untreated surgically menopausal women. Plasma estradiol, testosterone, total cholesterol, triglycerides, high-density lipoproteins, and low-density lipoproteins were measured at baseline (55 days after injection) and then on days 2, 4, 8, 15, 21, and 28 after injection. The plasma estradiol levels were greater in the two hormone-treated groups compared with the control group ($p < 0.01$), and plasma testosterone levels of the combined group exceeded those of the other two groups ($p < 0.01$) and remained above the normal female range for the duration of the study. There were no between-group differences in total cholesterol, triglycerides, high-density lipoprotein, or low-density lipoprotein values. Neither was the low-density/high-density lipoprotein ratio significantly different between groups at any of the test times. Therefore, the addition of testosterone to a long-term parenteral estrogen replacement regimen did not induce an increased atherogenic lipid profile compared with that produced by the parenteral administration of estrogen alone. (AM J OBSTET GYNECOL 1987;156:414-9.)

Key words: Estrogen, androgen, menopause, lipoproteins

It has been well established that atherosclerotic vascular disease is less frequent in premenopausal women than in men of similar age.[1] Although the mechanisms of action are not clear, this sex difference is thought to be related, at least in part, to effects of the sex steroids on lipid metabolism. The premenopausal lipoprotein profile that is characterized by higher high-density lipoprotein (HDL) cholesterol and lower low-density lipoprotein (LDL) cholesterol concentration compared with that of the male profile is considered antiatherogenic.[2] Moreover, oral estrogens administered to postmenopausal women have been shown to increase HDL and decrease LDL.[3]

We have previously demonstrated that surgically menopausal women who received an estrogen-androgen preparation parenterally as replacement therapy had fewer physical and psychological symptoms,[4] less depressed mood,[5] and increased levels of sexual functioning[6] compared with women who received estrogen alone. Because of the strikingly superior clinical efficacy of the combined drug compared with estrogen alone, it seemed important to determine whether the addition of androgen to a postmenopausal estrogen replacement regimen might affect lipoprotein metabolism in women thus treated. More specifically, our goal was to investigate (1) whether parenteral testosterone, administered in combination with long-term estrogen, would militate against the beneficial effects of estrogen on lipoprotein subfractions and/or (2) whether it would induce a malelike lipoprotein profile in treated women, thereby possibly increasing their risk of coronary heart disease.

Material and methods

Subjects. The participants in this study were three groups of women who had undergone a total abdominal hysterectomy and bilateral salpingo-oophorectomy for benign disease at least 2 years before recruitment into the study. Women in group 1 had been receiving an estrogen-androgen preparation intramuscularly once a month since operation. Group 2 was composed of women who were given a monthly injection of estrogen alone while women in group 3 had remained untreated since total abdominal hysterectomy and bilateral salpingo-oophorectomy at least 2 years ago. Subjects in the three groups were matched for age, weight, height, and years since operation. Fuurther selection criteria required that subjects be free of acute or chronic disease and that they not be receiving any other

medications. Women who ingested more than 6 ounces of wine or 2 ounces of liquor per day or who smoked were also excluded from the study. Subjects recruited from the McGill Menopause Clinic gave informed, signed consent by means of a form that had been approved by a university hospital ethics committee.

Procedure. A three (groups) by seven (time periods) design was used. The attempt was made to establish a baseline by which time the previous dose of hormones would have been as completely metabolized as possible. Accordingly, subjects in groups 1 and 2 were asked to delay injection of hormone(s) for 4 weeks beyond their usual monthly appointment. At the onset of the study, therefore, the women would not have received a hormone injection for approximately 56 days. Then 30 ml of blood was drawn by venipuncture for the measurement of plasma estradiol, testosterone, triglycerides, HDL, LDL, and total cholesterol. This first sample, taken approximately 56 days after hormone administration, was designated as the baseline measure. Subjects in group 1 were then injected with 1 ml of the estrogen-androgen drug they had previously been receiving and group 2 received the usual dosage (1 ml) of the estrogen-alone drug. Blood was subsequently sampled on days 2, 4, 8, 15, 21, and 28 after injection for assay of plasma hormone levels and lipoprotein subfraction concentrations. Untreated women in the control group had two blood samples taken 28 days apart for measurement of hormone and lipoprotein concentrations.

Drugs. One milliliter of the estrogen-androgen combined drug (Climacteron) and 1 ml of the estrogen-alone drug (Delestrogen) were administered intramuscularly once during the study to subjects in groups 1 and 2, respectively. These were the same drugs in the same recomended dosages as had been given to women in groups 1 and 2 monthly for approximately 2 years before this investigation. The specific constituents and dosages per milliliter of both hormonal preparations are as follows: For the estrogen-androgen combined drug (Climacteron), each milliliter contains 150.0 mg of testosterone enanthate benzilic acid hydrozone, 7.5 mg of estradiol dienanthate, and 1.0 mg of estradiol benzoate. For the estrogen-alone drug (Delestrogen), each milliliter contains 10.0 mg of estradiol valerate.

Plasma hormone levels. Thirty milliliters of blood was collected from each subject at each test time. Blood sampling occurred between 8 and 9 AM after an overnight 15-hour fast. Fifteen milliliters of blood was immediately centrifuged and the plasma was stored at −20° C for the hormone assays undertaken at the conclusion of the study. Plasma estradiol was measured in duplicate by radioimmunoassay with the use of an antibody raised to 17β-estradiol–succinyl-bovine serum albumin after extraction into ethyl ether; charcoal was used as the adsorbent.* The limit of the assay sensitivity was 5 pg/ml. Serum testosterone levels

were measured by means of the immuno-testosterone iodine 125 extraction method. The lower level of sensitivity of the testosterone ^{125}I assay in female serum was 0.1 ng/ml. All samples from each subject were measured twice in the same assay at the conclusion of the study.

Lipoprotein lipids. Serum triglyceride determinations were performed with the S.V.R. Enzymatic Triglycerides Tests obtained from Behring Diagnostica (La Jolla, California), based on the method of Bucolo and David. Total serum cholesterol was measured by an enzymatic technique with a reagent obtained from Fisher Scientific, Montreal, Quebec, Canada. Serum HDL cholesterol was determined according to a method of precipitation with polyanions described by Burnstein et al. LDL cholesterol was estimated by indirect calculation (LDL cholesterol = total cholesterol − [HDL + triglycerides/5]).

Statistical analyses. Hormonal and lipid data were analyzed with the use of BMDP analysis of variance for repeated measures for groups × time blocks. Within- and between-group Tukey post hoc tests were then used to probe significant group × time analysis of variance interactions when they occurred.

Results

Subject characteristics. Forty-two women participated in this study; 20 were in group 1, 11 in group 2, and 11 in group 3. As seen in Table I, there were no significant differences between the three groups for any of the matching variables we used initially. Moreover, all subjects were in good general health and none were currently receiving any medications except for hormones. Review of pathology reports of the subjects revealed that all of the women had undergone total abdominal hysterectomy and bilateral salpingo-oophorectomy for benign uterine fibroids. At the outset of the study, subjects were able to delay monthly injections for a mean of 55 days (range 52 to 55 days). Therefore, this period of time defines the baseline measure.

Plasma hormone levels. Mean plasma estradiol levels for the seven test times appear in Table II. Except for the baseline measure, estradiol values of both hormone groups exceeded those of the untreated control group at every test time ($p < 0.01$). Also, on days 2, 4, 8, and 15 after injection, women in the estrogen-alone group had mean estradiol levels that were higher than levels of those who received the combined estrogen-androgen drug ($p < 0.01$).

Analysis of plasma testosterone levels showed that values of the combined estrogen-androgen group exceeded those of both the estrogen-alone and the control group at every test time ($p < 0.01$) (Table III). Within-group analyses showed that the estrogen-androgen group's testosterone levels were greater on days 4, 8, and 15 after injection compared with baseline and postinjection day 28 values. However, testosterone levels of the estrogen-alone and the control groups remained stable throughout the course of the investigation.

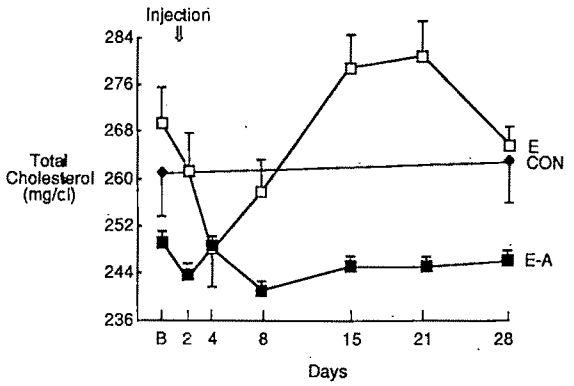

Fig. 1. Total cholesterol levels (mean ± SEM). *E* = Estrogen group; *CON* = control group; *E-A* = estrogen-androgen group.

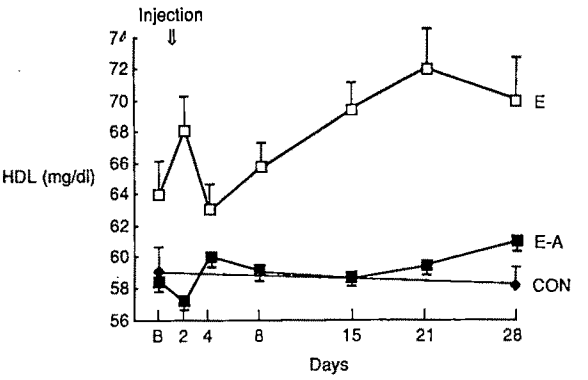

Fig. 2. HDL levels (mean ± SEM). *E* = Estrogen group; *CON* = control group; *E-A* = estrogen-androgen group.

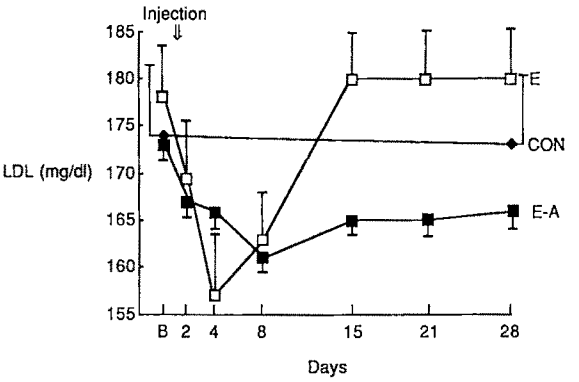

Fig. 3. LDL levels (mean ± SEM). *E* = Estrogen group; *CON* = control group; *E-A* = estrogen-androgen group.

Lipoprotein cholesterol. Total cholesterol levels of the three groups appear in Fig. 1. Although there were no significant differences between the cholesterol levels of the three groups at any of the test times, the analysis of variance did show a significant main effect for group ($p < 0.01$). Post hoc tests revealed that whereas total cholesterol levels of both the combined estrogen-androgen group and the control group remained quite stable throughout the treatment phase, values of the estrogen-alone group were lower on day 4 after injection compared with values on days 15 and 21 ($p < 0.05$). Analysis of triglyceride levels showed that there were no significant differences between the groups at any of the test times throughout the course of the study. Neither did triglycerides levels fluctuate in the two hormone-treated groups in association with changes in the circulating hormone levels as the drugs were being metabolized.

Differences in HDL levels between the groups also failed to attain statistical significance at any point in time during the study, as seen in Fig. 2. However, once again, the analysis of variance showed a main effect for group ($p < 0.02$). Within-group post hoc analyses showed that, in the combined estrogen-androgen group, HDL levels were lower on day 2 after injection than on day 28 ($p < 0.05$), and in the estrogen-alone group, HDL values were lower at baseline and on day 4 after injection than on day 21 ($p < 0.05$). Similarly, LDL levels also differed only within the two hormone-treated groups. As seen in Fig. 3, LDL was lower in the combined group on postinjection day 8 compared with baseline ($p < 0.05$). In the estrogen-alone group, LDL was lower on days 4 and 8 after injection compared with baseline values and values on days 15, 21, and 28 ($p < 0.05$).

Mean LDL/HDL ratios were computed for each group at each time period (Table IV). The analysis of variance on these data failed to find a significant interaction or main effect.

Comment

The major finding of this study was that the addition of testosterone to a parenteral estrogen replacement regimen for postmenopausal women did not adversely affect the lipoprotein cholesterol profile in these women compared with patients treated with parenteral estrogen alone and with bilaterally oophorectomized women who remained untreated. Before we discuss these results, several points need to be addressed.

The dosage of estradiol administered to the estrogen-alone group (estradiol valerate, 10 mg) and that administered to the combined estrogen-androgen group (estradiol dienanthate, 7.5 mg, and estradiol benzoate, 1 mg) both induced increases in plasma estradiol levels that remained significantly higher than baseline levels until postinjection day 15. The estrogen-alone drug induced higher estradiol levels than did the combined preparation for the first postinjection week, but at all times during the study, plasma estradiol levels were within the range of normally fluctuating menstrual cycle values in both hormone-treated groups.[7] These values also fall within the ranges that are thought to provide adequate protection against postmenopausal osteoporosis.[8] On the other hand, plasma testosterone levels of women who received the combined drug ex-

ceeded those of the estrogen-treated and the control groups at every point in time during the course of the investigation. These values also exceeded norms for ovulating women as well as the norms for women established in the laboratory that carried out these assays (0.2 to 1.2 ng/ml). It was also noted that plasma testosterone levels of the combined group were sustained at higher levels for a considerable period of time (83 days in this study). Although no other reports of the intramuscular administration of testosterone to women could be located, these findings are similar to those documented after implant therapy. In one such investigation, subcutaneous implantation of pellets containing 75 mg of estradiol and 75 mg of testosterone induced plasma testosterone levels that peaked at 2.5 ng/ml after 2 weeks.[9] Moreover, circulating testosterone levels in that study did not decrease to pretreatment values until 18 weeks after implantation. Plasma testosterone levels that exceeded female norms were also reported one month after subcutaneous implantation of 40 mg of estradiol and 100 mg of testosterone, and levels still remained elevated above the normal female limit by 6 months.[10] Our findings indicate that intramuscularly administered testosterone is also metabolized very slowly. Despite this, only one subject who received the combined drug had hirsutism that was characterized by a mild growth of hair on the chin and a moderate growth on the abdomen and legs. None of the other women had any signs of virilization as determined by direct questioning and by physical examination.

The evidence that testosterone decreases HDL and increases LDL, thereby creating an atherogenic lipid profile, is impressive. Firstly, life-span distribution of LDL and HDL in both sexes shows that HDL levels are lower in men than in women from puberty onward whereas LDL levels are higher in men than in women until menopause. Furthermore, the LDL/HDL cholesterol ratio is higher in men at all stages in the life-span although the risk ratio does narrow progressively with increasing age.[11] These sex differences in lipid profiles are thought to reflect the endogenous differences in concentrations of the sex steroids. Experimental manipulation of androgens in men supports this conclusion. Normal men who received a long-acting gonadotropin-releasing hormone analog for 10 weeks had acutely lowered plasma testosterone levels that were associated with significant increases in HDL and LDL cholesterol.[12] Conversely, male athletes who self-administered fairly large doses of anabolic-androgenic steroids both orally and intramuscularly experienced a significant decrease in HDL cholesterol and an increase in LDL cholesterol compared with the values when exogenous androgenic steroids were not being used.[13]

Several studies in women have also reported that hyperandrogenemia may result in a male pattern of lipoprotein lipid concentrations that could increase atherogenic potential. Women with polycystic ovary syndrome who had elevated testosterone levels also had lower HDL and higher LDL values compared with those of normal subjects.[14] When a normolipidemic postmenopausal woman was given an androgenic, anabolic steroid orally, HDL decreased while LDL increased.[15]

On the basis of the evidence of the effects of androgen on lipoprotein lipid concentrations, it might have been predicted that our subjects who had been receiving long-term estrogen and testosterone would have had lower HDL and higher LDL values compared with values of both estrogen-treated and untreated women, yet they did not. Several explanations of our findings are possible. First, it has by now been firmly established that the administration of exogenous estrogen to postmenopausal women increases HDL and decreases LDL.[2] The findings that HDL levels of the estrogen-alone group were significantly higher by day 21 after injection and that LDL levels were lower on days 4 and 8 compared with baseline values are consistent with previous reports. It is possible therefore that the specific doses of each of the sex steroids contained in the combined preparation we used exerted an equal and opposite effect on lipoprotein lipid concentrations such that the net effect was to maintain their stability. Alternatively, it is possible that between-group differences were not significant because of the greater variability in the estrogen-alone group that, in turn, was likely due to its smaller sample size. Confirmation of these findings therefore awaits replication with larger and equal sample sizes.

A third possible explanation of our findings is based on the suggestion that the route of administration may modulate responses to hormone therapy. Percutaneous and vaginal administration of estradiol do not cause the increases in triglycerides and very low–density lipoprotein observed during oral therapy.[16, 17] In the present study as well, intramuscular injection of estradiol did not induce changes in lipoprotein lipids compared with control values of untreated women. Furthermore, it has been shown that subcutaneous implantation of pellets containing 40 mg of estradiol and 100 mg of testosterone did not cause any changes in cholesterol, triglycerides, or HDL from pretreatment levels.[10] Farish et al.[18] likewise found that subcutaneous pellets of 50 mg of estradiol and 100 mg of testosterone had no effect on HDL fractions but testosterone appeared to slightly enhance the LDL cholesterol–lowering effect of estradiol as it seemed to do in the present study.

Despite the fact that no significant between-group differences were found, there are hints in these data that the exogenous testosterone may, at times, have induced a more malelike lipoprotein profile that was of short duration. For example, the depression in HDL

levels on day 2 after injection in the combined group may have reflected a transient androgenic effect. Also, in absolute terms, HDL levels were lower in the combined group compared with the estrogen group although this fell short of statistical significance. Finally, mean LDL/HDL ratios of the combined group were higher than those of the estrogen group at six of the seven test times although, once again, these too failed to attain statistical significance. Thus, if the exogenous testosterone we administered did have an effect on lipoprotein lipids, it was mild, transient, and of questionable clinical meaningfulness.

In summary, this study found that the addition of testosterone to a parenteral estrogen replacement regimen did not adversely influence the lipid profile of postmenopausal women thus treated for 2 years. This conclusion, however, applies to the specific doses and route of administration used in this study and cannot be generalized to other androgenic compounds or to other routes of administration.

Effects of adenosine 3′,5′-cyclic monophosphate, forskolin, and cholera toxin on hormone production in human term placental cells

Fuzhen Zhou,* Basil Ho Yuen, M.B., and Peter C. K. Leung, Ph.D.**
Vancouver, British Columbia, Canada

Trophoblast cells from human term placenta in monolayer culture were used to investigate the role of adenosine 3′,5′-cyclic monophosphate in the production of human chorionic gonadotropin and estradiol-17β. The intracellular concentration of adenosine 3′,5′-cyclic monophosphate was elevated by (1) addition of an adenosine 3′,5′-cyclic monophosphate analogue, 8-bromoadenosine 3′,5′-cyclic monophosphate, (2) inhibition of the hydrolysis of G_s-GTP complex by cholera toxin, and (3) direct stimulation of adenylate cyclase with forskolin. Addition of 2 mmol/L of 8-bromoadenosine 3′,5′-cyclic monophosphate markedly increased the accumulation of human chorionic gonadotropin in the culture medium on days 2, 3, and 4 of treatment. Likewise, addition of cholera toxin (0.2 μg/ml) or forskolin (50 μmol/L) also enhanced human chorionic gonadotropin production. On the other hand, the production of estradiol-17β was significantly inhibited by 8-bromoadenosine 3′,5′-cyclic monophosphate, at the same time that human chorionic gonadotropin production was enhanced in the same experiments. These results further support a differential role of adenosine 3′,5′-cyclic monophosphate on human chorionic gonadotropin and estradiol-17β production in the human term placenta. (Am J Obstet Gynecol 1987;156:420-4.)

Key words: Chorionic gonadotropin, human, placental cell culture, cyclic adenosine monophosphate

Although various factors that influence placental hormone production have been studied extensively,[1] controversies exist concerning the possible role of these factors. With regard to human chorionic gonadotropin (hCG), it has been shown that the production of hCG by trophoblast is stimulated by adenosine 3′,5′-cyclic monophosphate (cAMP).[2, 3] To our knowledge, the effects of other factors that perturb the cAMP-generating system at the cellular level (such as forskolin and cholera toxin) on hCG have not been investigated. The effects of cAMP on placental steroidogenesis appear to be more complex. While stimulation of trophoblast aromatase activity by cAMP has been demonstrated in choriocarcinoma cells,[2-4] cAMP inhibited estradiol-17β secretion in human term placental explants supplemented with dehydroepiandrosterone sulfate.[5] On the other hand, other investigators have shown that the addition of dibutyryl cAMP plus theophylline to the culture medium had no effect on aromatase activity 24 hours after its addition but decreased aromatase activity after 48 hours in placental cell culture.[6]

In view of the still confusing role of cAMP on placental hormone production, the purpose of this study is to examine the effects of exogenous cAMP, as well as forskolin and cholera toxin, on the production of hCG and estradiol-17β, with use of human term placental cells in monolayer culture.

Material and methods

Cell culture. The placental cells were prepared according to Hall et al.[7] and Branchaud et al.[8] with some modifications. The portions of term placental cotyledons obtained from cesarean section were transported in Hanks balanced salt solution without calcium and magnesium (Gibco) under aseptic conditions. The tissues were rinsed thoroughly with Hanks balanced salt solution and finely minced. The excess buffer was discarded following centrifugation at 50 × g for 5 minutes. Approximately 5 to 10 gm of tissue was then digested in 30 to 100 ml of 0.25% trypsin (Gibco) and deoxyribonuclease (500 U/100 ml, Sigma) in Hanks balanced salt solution. The digest was incubated at 37° C and agitated by hand intermittently every 5 minutes. After 10 to 15 minutes of incubation the supernatant

was transferred to centrifuge tubes containing 0.7 ml of fetal bovine serum (Gibco). The cells were harvested by centrifugation at 50 × g for 10 minutes. The supernatant was discarded. The pellet was covered by fetal bovine serum and kept in ice bath. This procedure was repeated up to six times. The large amount of erythrocytes was lysed by adding 10 ml of freshly made ammonium chloride–phosphate buffer (0.83% ammonium chloride in phosphate-buffered saline solution, pH 7.2) and kept in an ice bath for 8 minutes. One ml of fetal bovine serum was then layered onto the bottom of the tube carefully. The tube was centrifuged at 100 × g for 8 minutes. The pellet was washed once and resuspended in minimal essential medium (Gibco) with 10% fetal bovine serum. Aliquots of approximately 5×10^5 cells/ml were plated in 24-well cultured plates (Falcon) and incubated at 37° C in an atmosphere of 95% air and 5% carbon dioxide for 4 days. The culture medium was changed daily. The cells were treated with 8-bromoadenosine 3′,5′-cyclic monophosphate (8-Br-cAMP, 2 mmol/L, Sigma), forskolin (50 μmol/L, Sigma) or cholera toxin (200 ng/ml, Sigma). At the end of the experiment the culture medium samples were stored at −20° C until hormone measurements.

All experiments were performed in quadruplicate. Each sample of culture medium was assayed for hCG and estradiol-17β by radioimmunoassays, as previously described.[9] Measurement of hCG was made with the Amerlex β-hCG radioimmunoassay kits purchased from Amersham. Data for hCG are based on the second international standard. Results are presented as the mean ± SE. Statistical differences were determined by analysis of variance.

Results

As indicated in Tables I and II, basal production of hCG by the cultured placental cells increased markedly in a linear fashion from the low levels observed on day 1 of treatment (6.5 ± 0.6 mIU/ml and 7.2 ± 0.5 mIU/ml, respectively) to reach maximal hCG levels on day 3 (230 ± 14 mIU/ml and 113 ± 8 mIU/ml, respectively). This represents a 15- to 35-fold increase in hCG production in the control cultures over a period of 3 days. By contrast, the production of basal estradiol-17β in the same experiments was already maximal on the first day so that the levels of estradiol-17β in the control cultures were not significantly altered ($p > 0.05$) on days 2, 3, and 4.

Addition of 2 mmol/L of 8-Br-cAMP to the cultured placental cells markedly enhanced hCG production (Table I). The stimulation of hCG was already significant ($p < 0.01$) as early as 24 hours after 8-Br-cAMP addition, with the level of hCG at this time reaching

Table III. Effects of forskolin and cholera toxin on hCG and estradiol-17β secretion by human placental cells in monolayer culture

Treatment	*hCG (mIU/ml)*	*Estradiol-17β (pg/ml)*
Control	72.8 ± 5	514 ± 30
Forskolin	171.7 ± 11.1*	548 ± 53
Cholera toxin	124.9 ± 6.1†	560 ± 115

*$p < 0.01$.
†$p < 0.05$.

200% of that in control cultures. The stimulated level of hCG remained linear up to day 4 of treatment. On day 4 of 8-Br-cAMP stimulation the level of hCG was 160% of that observed in control cultures ($p < 0.01$). Similar results were obtained in at least three other separate experiments.

In sharp contrast to the stimulatory action on hCG production, the addition of 2 mmol/L of 8-Br-cAMP significantly attenuated estradiol-17β production in the same cultured placental cells. As indicated also in Table I, the inhibitory effect on estradiol-17β was observed as early as 24 hours after addition of 8-Br-cAMP (from 552 ± 67 pg/ml to 364 ± 27 pg/ml, $p < 0.05$). On day 4 of treatment the level of estradiol-17β in the 8-Br-cAMP–treated cultures was still significantly suppressed ($p < 0.01$) to 62% of the level observed in the control cultures.

Since forskolin activates adenylate cyclase directly to stimulate intracellular production of cAMP, we have examined the possible effect of forskolin on placental hCG and estradiol-17β production. It can be seen in Table II that 50 μmol/L forskolin, a dose previously shown to stimulate cAMP production in other tissues, markedly enhanced hCG production in cultured placental cells. Like 8-Br-cAMP, the stimulatory effect of forskolin was observed as early as 1 day after its addition to the cells ($p < 0.01$). On day 4, the forskolin-stimulated hCG level was 270% when compared with that found in control cultures ($p < 0.01$). Also, the addition of 10 μmol/L of forskolin was effective in stimulating hCG production in other experiments (not shown). On the other hand, addition of either 10 or 50 μmol/L of forskolin failed to significantly affect the levels of estradiol-17β on days 2, 3, or 4 of treatment ($p > 0.05$, Table II).

We next examined the possible effects of cholera toxin, which is also known to stimulate cAMP production. As in the previous experiments with forskolin, addition of cholera toxin to the culture medium (on day 1) also stimulated hCG production on days 2, 3, and 4 of culture. Results of a representative experiment are shown in Table III. Addition of cholera toxin (200 ng/ml) on day 1 caused a significant increase (170%) in hCG ($p < 0.01$) when compared with control cultures on day 2 of treatment. In the same experiment, 50 μmol/L of forskolin was slightly more effective than cholera toxin, stimulating hCG to 237% of control level on day 2 ($p < 0.01$). The degrees of hCG stimulation caused by cholera toxin and forskolin, however, were the same on days 3 and 4 of treatment (not shown). Like forskolin, the presence of cholera toxin also did not affect the production of estradiol-17β when compared with control cultures (Table III). Again, almost identical results were obtained in at least two other experiments.

Comment

The present results are consistent with previous reports that the production of hCG in trophoblast cells is stimulated by cAMP.[2, 3, 10] In this study the intracellular concentrations of cAMP is elevated by (1) the addition of a cAMP derivative, 8-bromo-cyclic AMP, (2) direct stimulation of adenylate cyclase with forskolin, or (3) inhibition of the hydrolysis of G_s-GTP complex by cholera toxin. In the present placental cell culture system, the basal hCG level reaches its peak value on day 3 and remained elevated on day 4 of the experiment. Addition of 8-Br-cAMP, forskolin, or cholera toxin markedly stimulated hCG production. This stimulation could be observed as early as 24 hours after treatment and persisted at least to the end of the study on the fourth day.

The role of cAMP in the regulation of hCG production is not clear. Khodr and colleagues[11, 12] have proposed that placental hormonal production could be affected by human chorionic gonadotropin–releasing hormone (hCGnRH) which is synthesized by cytotrophoblast. The stimulatory action of hCGnRH on hCG is believed to be cAMP-mediated. In support of this, a gonadotropin-releasing hormone receptor that activates cAMP has been reported in human placenta by Currie et al.[13] Also, it has been demonstrated that cAMP itself is accumulated after treatment of placenta with exogenous gonadotropin-releasing hormone. Thus the present finding of remarkably similar stimulation of hCG by 8-Br-cAMP, forskolin, and cholera toxin may well reflect a role of cAMP in the signal transduction of hCGnRH in the human placenta.

The influence of cAMP on placental estradiol-17β production is more controversial. In choriocarcinoma cells aromatase activity could be stimulated by cAMP.[2-4] Moreover, Hochberg et al.[14] reported that addition of dibutyryl cAMP to placental cell culture stimulated estrogen secretion. By contrast, Lobo et al.[6] failed to stimulate aromatase activity with the combination of cAMP and theophylline in human term pla-

cental cell in monolayer culture, while Haning et al.[5] reported that cAMP decreased estradiol-17β output in placental explants supplemented with dehydroepiandrosterone sulfate.

Unlike hCG, the production of estradiol-17β remained relatively unchanged throughout the 4 days of experiment in the present study. As no additional precursor steroids (for example, dehydroepiandrosterone sulfate) were added to the culture medium, estradiol-17β production by the placental cells was low and probably dependent on the very low concentrations of precursor steroids in the fetal bovine serum added. Nevertheless, in most experiments the concentration of estradiol-17β in the culture medium reached its peak value by day 2 and remained elevated above day 1 levels until the end of the study (that is, day 4). In contrast to its effect on hCG, the addition of 8-Br-cAMP to the placental cells caused a significant inhibition of estradiol-17β production. This latter effect occurred as early as 24 hours after the addition of 8-Br-cAMP and persisted throughout the entire 3 days of treatment. In placental explants, other investigators have proposed that the inhibitory effect of 8-Br-cAMP on estradiol-17β production may result from a possible blockade of steroid 3-sulfatase, the rate-limiting step of conversion of dehydroepiandrosterone sulfate to estradiol-17β in trophoblast cells.[5] In the present study, since the steroid precursors available to the placental cells from the fetal bovine serum were presumably low in concentration and certainly not all sulfated, the precise locus of inhibition caused by 8-Br-cAMP remains to be determined. Likewise, the failure of either forskolin or cholera toxin to affect estradiol-17β production is rather difficult to explain, especially in view of the present finding that both forskolin and cholera toxin were effective in stimulating hCG production in the same placental cells. On the assumption that steroid 3-sulfatase or aromatase is indeed affected by cAMP, the possibility exists that the intracellular concentrations of cAMP induced by forskolin or CT, while effective in enhancing hCG production, may not be sufficient enough to significantly perturb these enzymes in the placental cells. Further investigation is warranted to clarify this point.

More recently Siler-Khodr et al.[12, 15] have shown that, while synthetic gonadotropin-releasing hormone stimulates both hCG and estradiol-17β release from term placental tissue culture, the stimulation of hCG production by gonadotropin-releasing hormone only occurred after extended culture and when steroid levels were low. Likewise, Branchaud et al.[8] have found that the addition of dehydroepiandrosterone sulfate to the culture medium of placental cell cultures significantly inhibited the stimulatory action of gonadotropin-releasing hormone in hCG release. In the present study, 2 mmol/L of 8-Br-cAMP stimulated hCG release, while the production of estradiol-17β was inhibited in the same cultures. Thus it can be speculated that the modulation of placental production of hCG and estradiol-17β by cAMP, like gonadotropin-releasing hormone, may follow a reciprocal relationship. Further investigations will be needed to determine which specific enzymes are altered by elevated cAMP concentrations, as well as the possible causal relationship between gonadotropin-releasing hormone and cAMP action in the placental cells.

The excellent technical and editorial assistance of Ms. Joan Morgan and Miss Mary-Ann Ungless is gratefully acknowledged.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Clinical Opinion

Psychosis and pregnancy: Some new ethical and legal dilemmas for the physician

E. Earlene Dal Pozzo, M.D., and Frank H. Marsh, J.D., Ph.D.
Denver, Colorado

Physicians who treat women of childbearing age may encounter the presentation of psychosis in a pregnant woman that presents special problems in diagnosis and treatment, particularly ethical and legal considerations that center on the rights of the mother as well as the continually evolving definition of fetal rights. This article represents a collaborative effort to address these considerations. Representative case material from the treatment of a psychotic pregnant patient is presented with a focus on the nature of the contractual relationship of the treating physician with the mother and fetus. (AM J OBSTET GYNECOL 1987;156:425-7.)

Key words: Privacy, compelling interest, fetal viability, best interests, predicability of harm

Caring for a psychotic pregnant woman throughout her pregnancy presents special problems in diagnosis and treatment. Intrinsic to the treatment are compelling social, ethical, and legal considerations that center on the legal rights of the mother as well as the continually evolving definition of fetal rights. A central issue in the treatment relationship with a psychotic pregnant patient is whether that treatment relationship specifically and contractually includes the unborn fetus. If so, the treatment relationship may present areas of conflict between the expectations or rights of the woman and the potential duties owed to the fetus. Potential conflicts become apparent in those situations where the physician's duty to the fetus interferes with the mother's ability to exercise her right to privacy or other rights within the health care system and society.

In recent years the courts have distinguished a line of duty that runs directly from the physician to the unconceived and unborn child from that duty that runs to the mother (*Curlender v Bio-Sciences Laboratories* 106 p3d 814 [Cal App 1980]).[1] The rationale of these decisions is directly applicable to the relationship between the physician and pregnant woman and sets the stage for what is ethically and legally required of the physician. The following case report demonstrates the potential conflicting duties between the physician, the psychotic pregnant woman, and the fetus.

Case report

Ms. A, a 41-year-old single, white woman, was a former boarding home resident with a long history of recurrent psychiatric hospitalizations due to chronic schizophrenia. She was brought to the emergency room on a 72-hour mental health hold after she had been found huddled in a corner of her apartment with her schizophrenic boyfriend. They were surrounded by garbage and without food.

On physical examination she was found to be approximately 27 weeks pregnant. She had received no prenatal care. She repeatedly denied her pregnancy.

On the psychiatric unit she was agitated and uncooperative. She frequently paced the ward wearing a heavy coat, mumbling to herself. She complained of hearing "demons in the night."

The patient had not taken her neuroleptic medication for several months. She accepted low-dose neuroleptic medication on the unit and returned to her usual level of functioning, that is, calm but psychotic. She no longer denied her pregnancy, but she continued to experience auditory hallucinations and delusions about the role of God in her pregnancy. She specifically denied suicidal and homicidal ideation and any thoughts of harming her baby. She asked to be discharged to return to her boyfriend's apartment. At this point in previous hospitalizations, she would have been discharged to a boarding home.

During this hospitalization, a civil commitment was requested for 90 days despite the patient's request to

leave the hospital. The commitment was requested in order to prevent any possible harm to the fetus that might result from recurrence of denial or psychotic interpretation of symptoms or through the neglect of basic nutritional and medical needs.

After 11 weeks of inpatient care she was delivered of a normal infant without complications. She decided to relinquish the infant. She was discharged to a boarding home and the civil commitment was dropped.

The physician-fetus relationship

A critical legal decision related to the definition of the treatment relationship with the pregnant patient and fetus is the 1973 landmark abortion case of *Roe v Wade* (410 US 113 163, US 1973). The Supreme Court held that a pregnant woman has a constitutional right of privacy that permits her to end her pregnancy through abortion. However, the decision to terminate a pregnancy is reserved only for the woman and her physician "free of any interference by the state" up to the point of fetal viability, at which time the state may have a "compelling interest" in both the mother's life and that of the unborn fetus. In its deliberations the court reached the following conclusion regarding the state's interest: "With respect to the state's important and legitimate interest in potential life, the 'compelling' interest is at viability . . .."

Contributing to the issues surrounding fetal viability are the immense technologic achievements during the past few years in fetal medicine that have increased survival of premature infants to earlier and earlier gestational age.[2] These developments further complicate the determination of a point of fetal viability. Traditionally, in medicine the pregnant woman and fetus have been treated as a single unit or patient. In the *Roe v Wade* decision, a separate and "compelling" interest in the fetus is described by the court.

There is substantial legal precedent in support of a preconception and/or prebirth relationship of duty between a physician and a newborn infant or fetus (*Park v Chessin*, 60 A2d 80 [NY 1977]; *Renslow v Mennonite Hospital*, 367 NE2d 1250 [IL 1977]). The fact that a physician's negligence in failing to act occurred before a child's birth does not prevent recovery for prenatal injuries or for wrongful death of a fetus.

Additional cases address the response or intervention required of the physician by the state where the life or welfare of a viable fetus is at stake. The courts, as far back as 1964, held that harm to unborn children can be adjudicated through dependency and neglect proceedings. In the New Jersey case of *Raleigh Fitkin–Paul Morgan Memorial Hospital v Anderson* (201 A2d 537 [NJ 1964], *cert denied* 377 US 985 [1964]), the state intervened under a court order to require a pregnant woman to undergo blood transfusions, to save not only her life but the life of her unborn child as well. In the more recent case of *Jefferson v Griffin Spalding County Hospital Authority*, 274 SE2d 457 (GA 1981), a court order was obtained by the state to require cesarean section over the objections of the mother where the unborn child was suffering from fetal distress. From these cases, it is fairly clear that a mother unwilling to permit life-saving medical care for a viable fetus is potentially subject to state action. The extended implications of these holdings, which are critical to the physician caring for the psychotic pregnant woman, are that intervention may be required of the physician by the state after the first trimester and most certainly at a reasonable point of viability.

A physician treating a psychotic pregnant woman has a dual line of duty: one to the pregnant patient and one to the fetus. Each treatment relationship carries a twofold responsibility: (1) to perform and (2) to do so in an acceptable manner. With this dual mother-fetus treatment relationship, three moral and legal dictates form the core of the physician's duty to perform: (1) He will be competent and will perform in a competent manner; (2) this performance will always be within the guidelines of "best interests" as expressed through the minimization of harm; (3) the patient will not be abandoned.

While the first dictate, that of professional competency, is very important, particularly in malpractice law, it is not directly involved in the present discussion. It is the second and third dictates that bear directly on the treatment relationship between the physician, the psychotic pregnant woman, and the unborn fetus and in the end will require a response from him.

It is the dictate of the "maximization of good" and the "minimization of harm" that makes caring for the psychotic pregnant woman so difficult. The physician must walk a tightrope between the respective needs and "best interests" of the fetus and those of the psychotic woman. He is expected, on the one hand, to take those steps necessary, including but not limited to invoking state action, for the protection of the viable fetus. On the other hand, if he confines or retains in custodial care a person not dangerous to herself or another and who is capable of living safely in an available community alternative, he may be held liable for civil damages.[3] This situation is compounded both by the necessity of discerning what is an unreasonable risk to the fetus and by the seemingly inequitable fact that a nonpsychotic pregnant woman who may present a comparable risk to her fetus (for instance, use of cigarettes, use of drugs, neglect of basic nutritional and medical needs) would not be held or committed to any ward or institution until she gives birth to her baby.

The extent of intervention required when a risk to the welfare of a fetus has been determined has been

interpreted as ranging from civil commitment of the pregnant psychotic woman (*O'Connor v Donaldson,* 422 US 563 [US 1975]) to reporting the case to state authorities for dependency and neglect proceedings.[3] Anything less exposes the physician to possible criminal sanctions, not to mention extensive civil liability, for failure to act where a neglected or abused unborn child is involved.

There is no easy answer to this dilemma and any resolution remains a judgment call by the physician related to "maximization of good" and the "predictability of harm." It is quite possible, because of the increasing parameters of fetal viability, that a psychotic pregnant woman, as indicated in our case report, might be held for an ever-increasing period until term. Given a logical extension of this situation, it is also quite possible in the not too distant future that "normal" pregnant mothers will likewise face hospital incarceration in those cases involving nutrition and medical neglect.

Characteristics of menopausal women seeking assistance

Evelyn Anderson, R.N., Ph.D., Sonia Hamburger, B.A., James H. Liu, M.D., and Robert W. Rebar, M.D.
La Jolla, California

Using a questionnaire approach, we have determined the demographic, social, and clinical characteristics of the first 100 participants attending our menopause clinic. Of the respondents, 79% reported onset of significant physical symptoms and 63% significant emotional symptoms during the menopause. Among the participants, 65% had varying degrees of depression as determined by the Zung self-rating depression scale. This seemed to be more prevalent in patients with previous pelvic operations. Only half the women were on a regimen of estrogen replacement therapy, and most were receiving estrogen in an unopposed fashion. In our menopause clinic, more than half the women were over their ideal body weight, which is in contrast to the popular misconception that only thin women develop menopausal symptoms. Data from our patients suggest the need for multidisciplinary menopause clinics to adequately address the physical and emotional problems of menopausal women. (Am J Obstet Gynecol 1987;156:428-33.)

Key words: Menopause, estrogen replacement, depression

Menopause is of increasing importance to health professionals in terms of both preventive and clinical care of women in their later years. With the increase in life expectancy, the average woman now lives approximately one third of her life in the postmenopausal period. The rapid emergence of large numbers of menopausal women during the last several years has created the sudden need for information about the special medical problems of this group and the most appropriate ways to treat problems unique to the menopause.[1, 2]

We perceived a need to focus on the menopause as an area where sympathetic understanding, dissemination of information, and education of patients and health professionals would help women make decisions about hormonal replacement therapy and the quality of life during the transition to a mature life-style. In 1982, we conducted a 1-day symposium for lay individuals sponsored by the Department of Reproductive Medicine, University of California San Diego, School of Medicine, in an effort to determine what kind of assistance menopausal women required. Topics covered during the symposium included both physiologic and psychological aspects associated with the menopause. A questionnaire completed by 169 of the more than 200 participants strongly supported development of a clinic dedicated to the management of the menopause. Furthermore, responses favored development of a clinic along the lines of the model proposed by Utian.[1] To that end, we started a multidisciplinary outpatient service consisting of group discussions with four to six women, followed by personal counseling with each patient during the 4-hour clinic visit. Our findings with the first 100 women to attend this clinic are the basis for this report. The Menopause Clinic continues today in relatively unchanged form except for the personnel. Our data[3] strongly support our opinions that (1) large numbers of menopausal women suffer from a variety of physical and emotional problems unique to the menopause, (2) menopausal women lack accurate information about the menopause, and (3) the establishment of multidisciplinary menopausal centers is a meaningful and important undertaking.

Subjects and methods

Subjects. Since patients are either self-referred or referred by a physician, it is clear that the data arising from our Menopause Clinic do not necessarily represent a cross section of menopausal women but would be characteristic of such women who seek assistance. We must therefore emphasize that the conclusions we have drawn must be considered as representing our

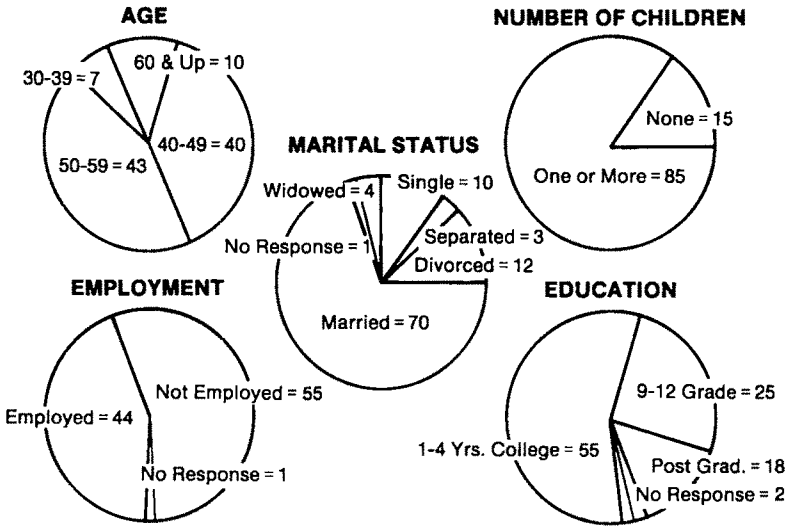

Fig. 1. Demographic distribution of patients seen at the Menopause Clinic from August 1982 to March 1983 by age, marital status, number of children, employment, and education (N = 100).

opinions since no controlled studies were conducted. Young oophorectomized women were neither excluded nor discouraged from attending. The demographic data are summarized in Fig. 1. Most of the first 100 women attending our Clinic from August 1982 to March 1983 were between the ages of 40 and 60 years (range 34 to 71), were currently married, had children, had some education following high school, and about half were employed.

The clinic setting. Participants interact with the health professionals of the clinic in an informal setting after completing a set of detailed questionnaires. Patients summarize their personal needs and, within a permissive and sympathetic atmosphere, are encouraged to share their problems, fears, and frustrations and to take increased responsibility for their own health care by developing a participatory relationship with their physician. Topics explored in depth include symptoms of the menopause, the advantages and disadvantages of hormone replacement therapy, stressing the importance of using progestins concomitantly with estrogens, osteoporosis, surgical menopause, nutrition, exercise, breast self-examination, and mammography. Each patient is given an annotated bibliography citing information about the menopause and related topics, a glossary of terms, a diary in which to keep relevant information on the menopause, dietary and exercise information, and a monthly record sheet on which to record symptoms related to the menopause. Patients are guided and assisted in the decision-making process, that is, whether to discuss hormone replacement therapy with their physician or to seek additional professional consultation from a psychiatrist, career counselor, or nutritionist as the final aspect of the clinic visit. The cinic staff includes a medical anthropologist, a nurse, and a physician with special expertise in reproductive endocrinology for consultation. A telephone number ("hot flash line") is available to patients requiring additional contact with staff. A listing of appropriate referral physicians is maintained for those individuals seeking another physician, but clinic participants are encouraged to share the information acquired with their regular physician. Answers to the questionnaires are made available to the physicians at the patient's request. Follow-up visits are not scheduled routinely but can be arranged on an individual basis if desired by the patient.

Questionnaires. On initial evaluation in the clinic, each patient is asked to complete a symptom checklist, the Zung self-rating depression scale,[4] and a questionnaire that identifies demographic data, family and personal history, height and weight, current medications, and a medical history with chief complaints. Six months later, follow-up questionnaires are mailed to both the patient and, where applicable, the spouse-partner. This survey includes questions about benefits of the menopause clinic visit, actions taken subsequently, and current adjustments with their partner.

Statistics. Data were analyzed with the Statistical Package for Social Sciences (McGraw-Hill). Differences between groups were evaluated with the use of χ^2, contingency coefficient, Kendall's tau, Student's t test, or Pearson's R tests; $p < 0.05$ was considered significant.

Results

Symptoms. The principal reason for attending the clinic varied among patients. Of the 100 participants 79% reported physical symptoms and 63% reported

Hot flashes	80
Muscle/joint pain	72
Headaches	68
Increased weight	65
Lightheadedness	58
Breast sensitivity	56
Increased appetite	50
Dizziness	49
Constipation	45
Numbness and tingling	45
Vaginal discharge	40
Genital pruritus	37

Table II. Distribution and frequency of emotional symptoms

Symptom	%
Irritability	93
Fatigue	91
Tension	91
Nervousness	88
Depression	86
Lack of concentration	82
Short temper	81
Lack of motivation	77
Early awakening	77
Insomnia	77
Loss of memory	75

emotional symptoms as the primary reason for attending the menopause clinic. Further information regarding such complaints was obtained from a symptom checklist. Hot flashes, pain in muscles and joints, headache, and increased weight were the most frequently cited physical symptoms, and irritability, fatigue, tension, nervousness, and depression were the most common emotional-cognitive disturbances (Tables I and II).

As a measure of psychological well-being, Zung self-rating depression scores were obtained for all patients; 35% of the participants had scores in the normal range with the remainder having scores indicative of varying degrees of depression (Table III). Of note is the observation that the Zung depression score was significantly higher ($p < 0.009$ by Student's t test) in those patients (44%) who had had prior extirpative pelvic operations than in those who had not. Thirty percent of all the women had undergone hysterectomy alone and an additional 14% had had hysterectomy and bilateral salpingo-oophorectomy.

Hormone replacement therapy. With regard to estrogen replacement therapy, 64% of women coming to the clinic had received estrogen at some time in the past. However, only about half of these, or 33%, were receiving any estrogen at the time of their clinic appointment. Most of the women using estrogen were receiving it in an unopposed manner without added progestin. More than half of the women with an intact uterus had received estrogen without progestin.

Exercise, weight, and height. Fifty-three percent of the women were obese, as determined from Metropolitan Life Insurance Tables.[5] The majority of women reported they did not exercise regularly. In fact, there was a statistically significant relationship ($p < 0.01$, χ^2) between routine exercise and normal weight; of those with normal weight, 63% exercised routinely, whereas the obese (33%) and grossly obese (28%) reported much less routine exercise. More than half the patients reported no change in height from age of 21; 31% noted a loss of ½ to 1 inch, and 11% reported a loss of 1 to 2 inches.

Sexuality. Only 40% of the women attending the clinic reported that they were satisfied with their sex lives. There was a statistically significant relationship between age and the frequency of intercourse ($p < 0.01$ by χ^2). Of women aged 40 to 49 years, 19% reported that they never or only infrequently had intercourse; this rose to 50% for those aged 50 to 59 years.

When the patients were questioned by mail 6 months later, those who had been satisified with their sex lives remained so. In contrast, dissatisfied patients were still dissatisfied regardless of whether they reported physical improvement with the new use of estrogen replacement. Male partners questioned by mail had quite different responses with regard to satisfaction with their sex lives; 100% of those men with relationships of <20 years reported that they were satisfied while only 50% of those with relationships of more than 20 years' duration reported satisfaction.

Follow-up assessment. Six months after attending the clinic, more than half the women reported that the reason for their appointment was primarily for education and support. Eighty percent of the patients felt that their clinic visit had been useful. Of those who had reported hot flashes, one third stated that their symptoms had become less frequent and/or less intense in the interim, in most cases as a result of the use of estrogen replacement. Almost half of the male partners felt that the menopause had had a negative effect on their relationships; the women were described as "touchy," with difficult mood swings and decreased sexual responsiveness. It should be noted that one third of the male respondents also stated that they themselves were involved in major midlife changes.

Comment

Information that we have accumulated at the Menopause Clinic at the University of California San Diego

Table III. Relationship between Zung self-rating depression score and surgical procedures (N = 95)

Total Zung score (range 30-89)	*Uterus and ovaries intact*		*Hysterectomy alone*		*Hysterectomy and bilateral oophorectomy*	
	n	%	*n*	%	*n*	%
Normal (30-49)	28	54.9	13	43.3	5	35.7
Mild depression (50-59)	15	29.4	7	23.3	6	42.9
Moderate depression (60-69)	5	9.8	5	16.7	2	14.3
Severe depression (>70)	3	5.9	5	16.7	1	7.1
Total	n = 51		n = 30		n = 14	

Medical Center has led us to reassess our approach to dealing with the problems of menopausal women. Many of our misconceptions were corrected by considering the data, although most of the findings were neither surprising nor unexpected.

The fact that 79% of those patients presenting with requests for assistance reported physical symptoms associated with the menopause certainly dispels the myth that "it is all in the head." The numerous objective measurements of hot flashes and their associated physiologic changes confirm the multiple effects of vasomotor instability.[6] The large number of emotional symptoms also reported by our patients strongly suggests the impact of physical complaints on the psyche.

The observation that 33% of the first 100 women presenting to the Menopause Clinic had moderate to severe depression on the basis of the Zung self-rating depression scale indicates the necessity of screening women with menopausal complaints for depression requiring professional care. The strong statistical relationship between depression by this objective scale and the patients who had undergone hysterectomy-oophorectomy suggests that many women undergoing pelvic operation either have not been reconciled to its necessity or were insufficiently prepared for the consequences. Clearly, education and support appear to be warranted both before and after such operations. Despite this observation, however, we would contend that the physical and emotional problems related to estrogen deficiency should be addressed first. Psychiatric treatment is not the first approach to the emotional lability of the menopause.

Classical endocrine teachings have stressed the association between obesity and the peripheral conversion of androgens to estrogens in fat.[7] Such data have led to the widespread conclusion that only thin women will complain of menopausal symptoms. The fact that more than half the women presenting to the clinic were overweight and that fully one fourth were at least 20 pounds overweight surprised us and quickly dispelled this misconception. It is clear that any postmenopausal woman, regardless of weight, may note symptoms related to the menopause. Since so many of our patients are overweight, we emphasize the importance of a calcium-rich, well-balanced diet and a program of regular exercise.[8] Diets should be scrutinized to ensure ingestion of approximately 1 gm/day of elemental calcium[9] in premenopausal women and in women receiving estrogen. For postmenopausal women not receiving estrogen, calcium intake should be increased to 1.5 gm/day. Exercise programs must be tailored to the individual woman. We also encourage regular activity emphasizing the many benefits relative to weight loss, prevention of bone loss, cardiovascular fitness, and mood.

One other common belief has been the notion that menopausal complaints tend to be more common in women suffering from the so-called "empty nest" syndrome, that is, homemakers depressed by the fact that their children have all left home. There was no statistical relationship between severity of depression and the presence or absence of children in the home. There were equal numbers of patients employed outside the home and homemakers. The majority of those employed were professional women who presented because their menopausal symptoms were interfering with their ability to function both outside and within the home. It was the rare patient, employed or unemployed, who expressed sadness or regret that her children had left home.

Not surprisingly, one of the major concerns of the patients revolved around the risks and side effects of hormone replacement therapy: uterine bleeding, weight gain, nausea, edema, breast tenderness, and fear of cancer.[10] Although almost two thirds of our patients had been prescribed estrogens previously, only half of those were still taking estrogen at the time of the clinic visit. Even those taking estrogen were sufficiently concerned about the use of the hormone to attend the clinic. Also of note is the observation that more than half the women taking estrogen who had intact uteri were taking it in an unopposed fashion without added progestin. Almost all of the women taking unopposed estrogen were prescribed this medication by a primary care physician other than a gynecologist. These data

are similar to a report from the Food and Drug Administration.[11] This last survey indicated that during the past 44 years, there appears to have been an increase in the use of progestins and estrogens together. Given the recognized risk of endometrial hyperplasia and carcinoma in women taking estrogen alone,[12, 13] the need for gynecologists to disseminate this information to other physicians is obvious. We believe that educating other physicians as to the benefits and risks of estrogen therapy is a responsibility that gynecologists must undertake and not abdicate.

Another major concern of our patients was the risk of osteoporosis in the postmenopausal years.[14] The only physical recordings that we take at our clinic are measurements of height and weight. We have used height loss as the basis for a discussion of osteoporosis, preventive considerations, and the likelihood of its development in individuals. We have chosen to leave to the patients' individual physicians the decision as to whether objective measurement of bone density is indicated. The risk of osteoporosis has led to intense interest in evaluating bone density in menopausal women. Several reliable noninvasive methods are available for evaluating bone density, and it is generally agreed that estimates of spinal bone density are more accurate as prognostic indicators than are estimates of appendicular (especially radial) bone density. We do not believe that bone density[15] need be estimated in all menopausal women. Rather we encourage measurement of spinal bone density by dual-photon absorptiometry in women at high risk for osteoporosis (that is, those who are white, slender, or receiving glucocorticoids, have a family history of osteoporosis, are cigarette smokers, have heavy caffeine and/or alcohol ingestion, or had early spontaneous or induced menopause) and in those who cannot or choose not to take estrogens in the postmenopausal years. However, because radiation exposure is so low with both dual- and single-photon absorptiometry, we do not feel that either of these procedures is contraindicated in any individual requesting an estimate of bone density. We do not make routine use of quantitative computerized tomographic scanning because of the radiation exposure (tenfold greater than with dual-photon absorptiometry) and the cost. There is probably no need for repeating bone density measurements more frequently than once a year.

In the follow-up questionnaire, the patients reported symptomatic improvement with the use of hormone replacement therapy. However, problems with their sex lives and with sleep generally persisted. It would seem that problems with sexual relationships do not automatically resolve with improvement in physical symptoms. The facts that the male partners often had different perceptions of the quality of the sexual relationship and that many of the men were themselves involved in midlife crises no doubt contribute to this observation. We routinely discuss sexuality in the postmenopausal years and encourage couples with difficulties to seek professional assistance. The difficulties with sleep also seem to have a multifactorial basis and have led us to discuss with our patients the differences between insomnia, early awakening, and intermittent sleep. Many of the patients complain of insomnia but on questioning merely awaken early after a sound sleep.

Experience with our Menopause Clinic has indicated that most women know very little about the menopause, and almost all felt that they had been helped by the clinic when questioned 6 months after the visit. Asked about the benefits of attending the Menopause Clinic, the responses were approximately equally divided among three of several choices: Some women were encouraged to seek medical care; others found relief in the knowledge that many women suffered from similar complaints; still others felt that they had gained helpful new information about the menopause. In any case these data support our belief that multidisciplinary centers for the menopause are needed and are of potential benefit.

Not only have the patients learned from the clinic but those of us health professionals involved with its operation have benefited as well. We believe that there are at least two important implications of our findings to the health care of menopausal women. First, each patient must be an informed partner in making decisions regarding therapy. Patients will no longer adhere to medical advice that has not been adequately explained and with which they therefore do not agree. This seems to be especially true with regard to treatment for the menopause, which is not life-threatening and in which the quality of life is involved. Women prescribed estrogens but not given sufficient information do not take them long. Second, treatment of menopausal problems must be individualized for the specific woman.

The Menopause Clinic described in this paper enables the gathering of longitudinal epidemiologic data at one center. Research on the effects of various treatments can be planned, developed, and evaluated. Screening for osteoporosis can be provided. All involved specialities (endocrinology, radiology, psychosocial, exercise physiology, nutrition, etc.) can be effectively coordinated. In the future, we believe, a well-woman's clinic for the climacteric would be the logical progression from the family planning clinic.

Progress is being made in bringing the subject of menopause "out of the closet" and disseminating research findings. However, optimal care of menopausal women requires the cooperation of a knowledgeable and sensitive physician with an interdisciplinary team

of health care professionals dedicated to the treatment of mature women.

We are grateful to Dr. S. S. C. Yen for his support and suggestions in the formation of the Menopause Clinic under the auspices of the Department of Reproductive Medicine. We are also indebted to the staff of the Menopause Clinic: Jeannette Fonseca, R.N., Lucy Bedard, R.N. (research assistant), Norma MacDaniels, L.V.N., Caroline Frazier, and Karen Gary. We also thank Del Alsobrook for her assistance with the manuscript.

Tocolysis with oral magnesium

Rick W. Martin, M.D., Donald K. Gaddy, M.D., James N. Martin, Jr., M.D., John A. Lucas, M.D., Winfred L. Wiser, M.D., and John C. Morrison, M.D.
Jackson, Mississippi

Seventeen patients in whom uterine activity responded favorably to parenteral magnesium sulfate were given oral magnesium gluconate for continued tocolysis. The mean serum magnesium level before therapy was 1.44 ± 0.22 mg/100 ml, whereas 2 hours after initiation of oral magnesium it was 2.16 ± 0.32 mg/100 ml ($p < 0.05$). One patient had nausea without vomiting or diarrhea. These data suggest that magnesium ingested orally can raise the serum magnesium level significantly. (Am J Obstet Gynecol 1987;156:433-4.)

Key words: Preterm labor, tocolysis, oral magnesium

After uterine activity is abolished with parenteral magnesium sulfate, patients are usually given β-adrenergic receptor agonist drugs orally for continued inhibition of contractions.[1] Magnesium salts are not administered for tocolysis because of gastrointestinal side effects. Because oral therapy with β-sympathomimetics is expensive and often complicated by cardiovascular problems,[2] we undertook a study to observe the effect of oral magnesium gluconate administered for tocolysis in patients with arrested uterine activity.

Seventeen patients with documented preterm labor were entered in this study from July 1 through September 30, 1985. On admission, a baseline serum magnesium level was obtained. Each patient was given a bolus and then continual magnesium sulfate intravenously (2 to 3 gm/hr) until uterine activity ceased. All patients in whom effective tocolysis was achieved with intravenous magnesium sulfate were eligible for inclusion in the study. Informed consent was obtained before oral magnesium therapy. All of those eligible agreed to participate. Once tocolysis was effective in reducing uterine activity to less than one contraction every 15 minutes for a period of 4 to 12 hours, the parenteral magnesium was discontinued. After this, 1 gm (two 0.5 gm tablets) of magnesium gluconate was administered to each patient orally every 4 hours. A serum magnesium level was obtained 2 hours after an oral dose of magnesium gluconate between 12 and 24 hours after discontinuation of parenteral magnesium sulfate. Patients were observed for uterine activity and for any evidence of gastrointestinal side effects. Statistical analysis of serum magnesium levels in these patients was performed by the Student paired t test with $p < 0.05$ being considered significant.

The mean serum magnesium level before any therapy was 1.44 ± 0.22 mg/100 ml. Two hours after 1 gm of magnesium gluconate was administered orally, the mean level was 2.16 ± 0.32 mg/100 ml ($p < 0.05$). No patient developed any signs of magnesium toxicity whether the agent was administered parenterally or orally. There was one patient who had nausea but vomiting did not develop and no subject had diarrhea at this dosage of magnesium gluconate. No repeat episodes of preterm labor occurred during this hospitalization.

These data reveal that oral magnesium gluconate can be administered to patients after tocolysis with parenteral magnesium sulfate and that a statistically significant increase in magnesium levels occurred when compared with the pretreatment value. It is possible that the elevated levels might have been due to the previously administered intravenous magnesium sulfate even though 12 to 24 hours had elapsed between discontinuance of the parenteral drug and sample collection. Therefore, we studied five patients in whom labor was arrested with magnesium sulfate as in the above patients but in whom oral β-sympathomimetic agents were given for continued tocolysis. In these five study subjects a level not significantly different from pretreatment values was obtained within 12 to 24 hours after the magnesium sulfate was discontinued (1.57 ± 0.29 mg/100 ml). Thus it would appear that the elevation in magnesium levels noted in our patients does indeed reflect the ingestion of oral magnesium gluconate.

Of special note is that only one patient complained of nausea and she did not have vomiting. In addition, there were no cases of diarrhea, which is another complication that may occur after such therapy. Also at these serum levels there were no cases associated with symptoms of systemic magnesium toxicity. Therefore magnesium gluconate administered in this fashion appears to be safe and relatively free of adverse side effects.

Finally, this drug, while safe, may or may not be an effective oral tocolytic. Reports in the European literature suggest that other forms of oral magnesium (oxide and peroxide) are effective.[3] In our patients, none of the 17 developed recurrent uterine activity or required further parenteral treatment. Nevertheless, since the level of magnesium after oral therapy was much less than the "therapeutic" range (4 to 8 mg/100 ml) found in those treated with parenteral magnesium sulfate for preterm labor or pregnancy-induced hypertension, it remains unclear whether oral treatment with magnesium gluconate will be a clinically effective modality. If it is shown to be an adequate tocolytic, then it will certainly be more cost-effective than β-adrenergic receptor agonist therapy since the cost of ritodrine hydrochloride is approximately $62 per week as compared with the magnesium gluconate expense of $7 for 7 days.

Maternal hypothermia: An unusual complication of magnesium sulfate therapy

John F. Rodis, M.D., Anthony M. Vintzileos, M.D., Winston A. Campbell, M.D., Jeffrey L. Deaton, M.D., and David J. Nochimson, M.D.

Farmington, Connecticut

Reported is a case of maternal hypothermia associated with magnesium sulfate therapy for treatment of preterm labor. Hypothermia was accompanied by fetal and maternal bradycardia. After discontinuation of magnesium sulfate infusion, maternal temperature, pulse, and fetal heart rate gradually returned to normal. No adverse effects were noted on either maternal or fetal outcome. (AM J OBSTET GYNECOL 1987;156:435-6.)

Key words: Hypothermia, magnesium sulfate

Magnesium sulfate is commonly used in the treatment of preeclampsia and preterm labor. Known maternal side effects are respiratory depression, electrocardiogram abnormalities (increased P-R interval, prolonged QRS interval, increased T wave), depression of deep tendon reflexes, and cardiac arrest.[1] To the best of our knowledge this is the first case report of maternal hypothermia secondary to magnesium sulfate therapy.

Case report

B. H., a 30-year-old woman, gravida 7, para 2-1-3-3, was transferred to the University of Connecticut Health Center at 30⅚ weeks' gestation because of preterm labor. Past obstetric history was significant for a preterm vaginal breech delivery, two spontaneous vaginal deliveries at term, a molar pregnancy, and two elective first-trimester abortions.

Physical examination revealed an oral temperature of 99.8° F, pulse 80 bpm, respirations 20/min, and blood pressure 130/70 mm Hg. Careful speculum examination revealed the cervix to be closed and uneffaced with no vaginal bleeding noted. Ultrasound revealed a single viable fetus in a vertex presentation with a complete placenta previa. Amniotic fluid volume appeared adequate. Estimated fetal weight was 1825 gm. Fetal biophysical profile was reassuring. An external fetal monitor revealed uterine contractions every 8 to 10 minutes and a baseline fetal heart rate of 140 to 150 bpm.

The patient received Celestone, 12 mg intramuscularly, to promote fetal pulmonary maturity and a 4 gm intravenous loading dose of magnesium sulfate. A maintenance infusion of magnesium sulfate was initiated at a rate of 2 gm/hr. Persistent contractions necessitated an increase in the infusion to 3 gm/hr, which eliminated all uterine activity. After 2 hours at the new infusion rate the serum magnesium level was 5.2 mg/dl. Maternal vital signs were oral temperature of 97° F, pulse 94 bpm, and blood pressure 120/80 mm Hg.

Twelve hours after admission the fetal heart rate was noted to be 110 bpm. The maternal vital signs were rectal temperature 95.8° F, pulse 64 bpm, blood pressure 90/50 mm Hg, and respirations 18/min. The patient complained of lethargy and diplopia. In spite of a serum magnesium level of only 6.6 mg/dl, the magnesium sulfate infusion was discontinued.

During the next 6 hours the patient's visual and cerebral abnormalities cleared. Maternal temperature slowly increased, and 6 hours after cessation of magnesium sulfate therapy vital signs were temperature 98° F, pulse 80 bpm, and blood pressure 120/60 mm Hg. No uterine contractions or bleeding was noted and baseline fetal heart rate returned to 130 to 140 bpm with normal variability.

Forty-eight hours after admission the patient had an episode of heavy vaginal bleeding, uterine contractions, and fetal tachycardia. A primary cesarean section was performed. A 1790 gm female infant was delivered with Apgar scores of 3 and 8 at 1 and 5 minutes, respectively. Arterial and venous cord pH values were 7.28 and 7.35, respectively. Placental cultures taken were later reported positive for *Listeria monocytogenes.*

Comment

In humans, body temperature is maintained within a narrow range despite extremes in environmental conditions and physical activity. The control of body temperature is a function of cerebral centers located in the hypothalamus. Oral temperatures <96° F are rarely encountered.[2] Rectal temperatures are usually 0.5° to

1.0° F higher than oral values. When there is a strong stimulus for heat production, muscle activity may increase to the point of shivering or even to a generalized rigor.

Instillation of cool intravenous fluids could have caused the observed hypothermia, but this is an unlikely cause in this patient. The fact that the temperature gradually returned to normal after discontinuation of magnesium sulfate, even though the total infusion rate remained constant, implicated the drug rather than the fluids as the source of hypothermia.

Hypothermia may also occur in patients with myxedema or infection. Since the patient was clinically euthyroid before and after the episode of hypothermia and had no history of thyroid disease, these are unlikely causes. Despite the recovery of *Listeria monocytogenes* from the placenta, the prompt resolution of hypothermia after cessation of magnesium sulfate therapy would support that magnesium sulfate rather than infection was the cause of the significant decrease in body temperature in this patient.

In conclusion, it appears that maternal hypothermia may be a complication of intravenous magnesium sulfate administration. One could hypothesize that magnesium sulfate might act centrally at the hypothalamic level or peripherally at the motor end plate to suppress muscle activity, hence causing decreased heat production that results in hypothermia. It is possible that milder degrees of hypothermia occur more commonly in patients receiving magnesium sulfate. However, this may not be brought to the attention of the physician, especially in the setting of severe preeclampsia or premature labor, when the attendant would be most concerned with other vital signs. The effect of magnesium sulfate on maternal temperature regulation appears to be reversible and does not seem to be associated with significant maternal or neonatal morbidity.

Plasma progesterone concentration in women with and without adenocarcinoma of the endometrium

Andrew P. Bond, M.D., Michael J. Diver, M.Sc., and J. Collinson Davis, M.D.
Liverpool, England

In the search for the postulated but elusive "estrogenic bias" in patients developing endometrial cancer, several authors have suggested lack of progesterone as the common denominator. In this study 21 patients at the time of diagnosis of Stage I disease are compared to stringently matched healthy control subjects. No significant difference was found in plasma progesterone concentrations between the two groups. These results, in conjunction with other calculated estrogenic indices based on these patients, provide no evidence of lack of progesterone at the onset of clinical disease. However, the effects of long-term progesterone lack related to chronic anovulation are not excluded by these findings. (Am J Obstet Gynecol 1987;156:437-40.)

Key words: Progesterone, uterine neoplasms, endometrium

Indices of estrogenicity in patients with endometrial cancer have been measured with use of a variety of endocrine parameters. Based on estrogen or androgen production[1-4] and transport,[5, 6] these measurements, when adequately controlled for body mass, tend to reveal little or no "estrogenic bias" in patients developing the disease. Gambrell,[7] along with other authors,[8-9] has presented the case for progesterone lack rather than estrogen overproduction as being the key to this elusive estrogenicity. It was therefore decided to assess the progesterone status of women at the diagnostic phase of Stage I disease and compare it with that of stringently matched control subjects.

Material and methods

Patient sample. Twenty-one patients presenting with FIGO Stage I cancers were matched with controls without endometrial-cancer for the principal epidemiologic parameters associated with the disease (Table I). Adequacy of matching was demonstrated by the detection of no significant difference between the groups for the parameters of age (t, paired = 0.256, $p > 0.5$), years since menopause (t, paired = 0.724, $0.5 > p > 0.1$), bulk index (weight/height^2)[11] (t, paired = 0.622, $p > 0.5$), and parity ($\chi^2 = 4.48$, $p > 0.5$).

Venipuncture was performed before noon and before any diagnostic or therapeutic procedure.

Progesterone assay. A danazol displacement assay was modified to embrace the range 0.080 to 4.90 ng/ml.[12] The following reagents were used: rabbit anti-progesterone α-hemisuccinyl conjugate (a gift from Dr. J. Corrie); danazol in crystalline form (Sterling-Winthrop); iodine 125–progesterone α-glucuronyl-tyramine (Amersham International); sheep antirabbit serum in cellulose matrix (Sac-cel, Wellcome Reagents Ltd.). Assay details are available from us. Definitive quality control experiments produced an intra-assay coefficient of variation of 4.2%. All samples in the study were assayed as a single batch with reference high and low controls.

Statistical analysis. Results were compared with use of Student's one-tailed t test on log values of plasma concentration. As a nonparametric check, the Wilcoxon rank sum test was also employed.

Results

The results are summarized in Table II. They indicate no significant difference in plasma progesterone concentration between the two groups. Plainly, patients F3 and C7 were mistaken concerning their menopausal status. However, even if these suboptimally matched pairs are excluded from the comparison, the difference remains nonsignificant.

Comment

The theory of progesterone lack is based on the cumulative effects of chronic anovulation. To measure progesterone levels at a single point in time, as in this study, is therefore not an appropriate test of the theory, which remains unchallenged by the findings. However, since estrogenic stimulation is more likely to promote than actually initiate mutation of an endometrial cell,[13] it is reasonable to suppose that such an influence would still be present, albeit attenuated, at the time of diagnosis.

Significance: $t = 0.74$, $0.25 > p > 0.2$—NS (Student's one-tailed t test). $z = 0.969$, $0.5 > p > 0.1$—NS (Wilcoxon rank sum test). If pairs D11/C7 and F3/H4 are excluded, $t = 1.0069$, $0.15 > p > 0.1$—NS.

*Verified on routine laboratory assay.

In the postmenopausal woman the adrenal gland is the sole significant source of production of progesterone, and this serves as a precursor of the adrenocortical steroids. Its relevance to the senescent endometrium is therefore questionable. However, considering the apparent changes in molecular structure of the estrogen receptor in the aging rat endometrium[14] in the presence of retained binding capacity of progesterone recep-

*Not significant.

tors,[15] it may be that a baseline production of progesterone is still necessary to maintain endometrial quiescence.

This is the first comparative study of plasma progesterone concentration in women with and without endometrial cancer to be reported in the literature. Of course, to measure progesterone in plasma is to gain only a rough guide as to the total endocrine "signal" being delivered to the endometrium. In the same group of patients and controls, we have assessed several other parameters[16] (Table III). Measurement of percent of free progesterone, percent of free estradiol, and total plasma estradiol level revealed no significant difference between the groups. When estradiol/progesterone ratios were calculated, the former having been corrected for measured sex hormone–binding globulin capacity and relative metabolic clearance, there were again no significant differences. It would therefore seem that in common with other indices of estrogenicity in endometrial cancer, the theory of progesterone lack does not translate well into hard endocrinologic data.

Predictive value of CA-125 levels in advanced ovarian cancer

Bruce Patsner, M.D., and Thomas G. Day, Jr., M.D.
Louisville, Kentucky

Thirty-eight patients with advanced ovarian cancer were monitored with serial serum CA-125 levels until second-look laparotomy or disease progression. Eleven of 15 patients had normal CA-125 levels but positive findings at second-look operation; two had normal levels despite progression of disease. Normal levels do not reliably predict absence of disease. (AM J OBSTET GYNECOL 1987;156:440-1.)

Key words: Ovarian adenocarcinoma, serum CA-125, second-look laparotomy

Recent efforts in tumor immunobiology have resulted in the development of monoclonal antibodies, one of which, OC-125, has been raised against an antigen (CA-125) that is present on the surface of most but not all invasive ovarian epithelial cancers and can be measured in the serum of the patient. This study reports the experience of the Division of Gynecologic Oncology of the University of Louisville School of Medicine with this assay.

Methods and material

Thirty-eight patients with histologically verified invasive ovarian adenocarcinoma (34 serous or anaplastic, one mucinous, one borderline) underwent cytoreductive operation by the Gynecologic Oncology service at the University of Louisville School of Medicine. PAC chemotherapy (cisplatin, Adriamycin, Cytoxan) was administered monthly for a total of 12 courses or until disease progression was documented. Serum CA-125 levels were determined at each visit and measured in the same laboratory according to previously described standard immunoradiometric techniques.[1] A CA-125 level >35 U/ml measured against a known reference standard defined an elevated value. No knowledge of patient disease status was known by the technicians performing the assay, and results of each test were not known to the authors at the time of examination of the patients.

Second-look laparotomy was defined as a full surgical evaluation in a patient who had completed all twelve courses of chemotherapy and had no evidence of disease on complete physical examination and radiologic evaluation. Only positive washings or biopsy specimens were considered evidence of disease.

Results

Twenty-six patients completed 12 courses of PAC chemotherapy and were eligible for second-look laparotomy. Five patients refused operation and all remain without clinical evidence of disease, with normal CA-125 levels and mean length of follow-up of 12 months. Of the remaining 21 patients, six had negative second-look laparotomy and all six had normal preoperative CA-125 levels. One of these patients developed an elevated CA-125 level 1 month before recurrent disease was detected clinically. Fifteen patients had biopsy-verified disease at second-look laparotomy. Eleven (73%) of these patients had normal CA-125 levels at the time of operation although one had a borderline serous tumor. Eight patients had disease <2 cm, one had microscopic disease, and two had 5 cm abdominopelvic tumors. Of the four patients with elevated CA-125 levels at the time of second-look operation, all had levels in the 40 to 75 U/ml range, and none had tumor larger than 2 cm although several had diffuse intra-abdominal carcinomatosis.

Seven patients had failure of first-line chemotherapy. CA-125 levels in five of these patients never fell to normal ranges after operation despite absence of clinical

disease. Two patients never had elevated CA-125 levels despite massive progression of disease with bone and liver metastases and intra-abdominal carcinomatosis. Five patients are receiving first-line chemotherapy and remain without evidence of disease. CA-125 levels fell to normal in this group of patients within three courses of chemotherapy.

Comment

On the basis of the current literature[2] it appears that an elevated serum CA-125 level is more predictive of disease status than a normal level. The results of this study are in agreement with this: No patient with a negative second-look laparotomy had an elevated CA-125 level, and all patients with an elevated level had disease discovered at operation. Unfortunately, 73% of patients with no clinical evidence of disease and normal CA-125 levels had biopsy-verified persistent disease at second look, and two patients who developed extensive disease while receiving first-line therapy never had an elevated CA-125 level. Thus second-look operation cannot be obviated in patients with negative examinations and normal CA-125 levels if such are to be used in deciding whether chemotherapy is to be discontinued. A rising level may, however, be an indication for surgical intervention to document and debulk tumor even in the presence of a normal clinical examination, in order to maximize the efficacy of second-line therapy.

The presence of normal CA-125 levels in patients with extensive occult disease (5 cm) is disturbing and suggests a possible limitation of use of laparoscopy alone as a second-look procedure.

Sonographic determination of fetal weights in diabetic pregnancies

Carol B. Benson, M.D., Peter M. Doubilet, M.D., Ph.D., and Daniel H. Saltzman, M.D.
Boston, Massachusetts

Accurate antenatal diagnosis of the macrosomic infant of a diabetic mother should lead to a decrease in perinatal morbidity. Several formulas for weight estimation based on sonographic measurements are in common use, but none of them has been devised specifically for the infant of a diabetic mother. We assessed the accuracy of conventional formulas at estimating fetal weight in 160 of these infants and found their relative errors (error as a percentage of birth weight) had standard deviations of 12.2% to 13.1% (greater than has been reported in the general population) with no statistically significant difference among formulas. We also devised customized formulas generated from a "training set" of 80 patients and tested on a second set of 80 patients. The best formula yielded a standard deviation of 11.0%. The difference between customized and conventional formulas was not statistically significant. With use of one conventional formula, the likelihood of macrosomia was found to be 77% when the estimated weight was >4000 gm and 86% when the estimated weight was >4500 gm. We conclude that fetal weight prediction is even less accurate in the infant of a diabetic mother than in the general population and that "customized" formulas fare no better than conventional formulas in diabetics. Despite this, estimated weights can offer guidance in predicting fetal macrosomia and therefore aid in obstetric management. (AM J OBSTET GYNECOL 1987;156:441-4.)

Key words: Diabetes, pregnancy, ultrasound

From the Departments of Radiology and Obstetrics and Gynecology, Harvard Medical School, Brigham and Women's Hospital, and the Joslin Clinic.
Received for publication April 4, 1986; revised July 17, 1986; accepted August 19, 1986.

Accurate antenatal diagnosis of the macrosomic (birth weight >4000 gm) infant of a diabetic mother should lead to a decrease in perinatal morbidity. The identification of these fetuses at high risk for traumatic birth injuries would allow for an elective cesarean section as the most appropriate and prudent route of de-

livery.[1] While several formulas for weight estimation based on sonographic measurements have been proposed,[2-5] none of those in common use have been devised specifically for fetuses of diabetic mothers. Since the body habitus of the infant of a diabetic mother is known to differ from the nondiabetic population, we undertook a study to assess the accuracy of conventional weight formulas in fetuses of diabetic mothers and to determine whether formulas specifically designed for diabetic mothers outperform conventional formulas in such fetuses. In addition to examination of the accuracy in prediction of actual fetal weight, a further goal was to determine the ability of current formulas to diagnose or exclude macrosomia.

Material and methods

Case material. We evaluated the sonographic examinations and obtained birth weights of 160 fetuses of diabetic mothers scanned within 1 week of delivery at our institution between January 1983 and February 1985. Specifically excluded from the study were twins and fetuses with congenital anomalies at birth.

All patients studied were insulin-dependent diabetic women before pregnancy or were gestational diabetic women diagnosed by abnormal glucose tolerance testing during pregnancy.[6]

Data collected. The sonographic examinations were performed with use of real-time sector scanners. Measurements collected on all fetuses included biparietal diameter (BPD), femur length (FL), and transverse and anteroposterior abdominal diameters (AD_1 and AD_2). Occipitofrontal diameter (OFD) was obtained whenever possible. The abdominal circumference (AC) was calculated by the formula

$$AC = (AD_1 + AD_2) \times 1.57$$

When the OFD was available, the corrected BPD[7] was calculated and used in place of the BPD in all formulas. Review of all ultrasound studies was performed without knowledge of neonatal birth weight.

All fetuses were weighed at birth. To account for fetal weight gain between the time of sonographic measurements and the date of birth, the actual fetal weight at the time of the examination was assumed to be the birth weight minus 30 gm for each elapsed day. (Thirty grams is the approximate daily weight gain in the third trimester.[8])

Evaluation of current formulas. We evaluated formulas of Warsof et al.,[2] Shepard et al.,[3] and Hadlock et al.[4] (We refer to the formula labeled E2 in Shepard et al.[3] as the "Shepard formula." The "Hadlock formula" used contains the variables AC × FL, BPD^2, AC, and FL.) We determined the error made by each formula on each of our 160 cases by taking the difference between the weight predicted by the formula and the actual weight. The relative error, the error expressed as a percent of the actual weight, was also calculated. The mean and standard deviation of the errors and relative errors were computed for each formula. The F test was used to compare formulas. We evaluated these current formulas:*

Warsof et al.[2]:

$$\log_{10}(FW) = -1.599 + 0.144(BPD) + 0.032(AC) - 0.111(BPD^2 \times AC)/1000$$

Shepard et al.[3]:

$$\log_{10}(FW) = -1.7492 + 0.166(BPD) + 0.046(AC) - 2.646(AC \times BPD)/1000$$

Hadlock et al.[4]*:

$$\log_{10}(FW) = -1.5213 - 0.003343(AC \times FL) + 0.001837(BPD)^2 + 0.0458(AC) + 0.158(FL)$$

where FW = Birth weight (kg), BPD = biparietal diameter (cm), AC = abdominal circumference (cm), and FL = femur length (cm).

Generation and assessment of new formulas. We divided our diabetic population into two equal groups of 80 patients each. The first group ("training set") was used to generate new weight-prediction formulas and the second group ("test set") to evaluate these formulas.

Formulas were generated from the training set of 80 cases by means of computer-assisted multiple regression analysis. For each formula, the dependent variable was $\log_{10}(FW)$ or FW, and a combination of fetal measurements was used as the independent variables. In particular, we developed a "Warsof-variant" formula by using the terms BPD, AC, and $BPD^2 \times AC$—the same terms used in the Warsof formula—as the independent variables. "Shepard-" and "Hadlock-variant" formulas were generated in a similar fashion. Four other formulas, with use of different combinations of measurements and independent variables, were also generated.

These formulas were then assessed on the test set by use of the same methods as were described in the previous section for evaluating current formulas.

Results

The performance characteristics of current formulas in our set of 160 diabetic mothers are presented in Table I. The Shepard and Hadlock formulas had very low systematic errors, in that their mean errors and mean relative errors were small. The standard deviation of the relative error, a measure of a formula's precision at predicting weight, was slightly lower with use of Hadlock et al.'s formula (±12.2%) than that of Warsof et al. (±12.6%) or Shepard et al. (±13.1%). The difference, however, was not statistically significant ($p > 0.05$).

*The constant term (−1.5213) differs from that used in Hadlock et al.[4] (1.4787) because we are expressing weights in kilograms instead of grams.

Table I. Performance characteristics of current formulas (mean ± SD)

Formulas	*Error (%)*		*Error (gm)*	
Warsof et al.	5.9 ± 12.6	*	242 ± 441	*
Shepard et al.	1.6 ± 13.1		102 ± 441	
Hadlock et al.	2.6 ± 12.2		124 ± 427	

*No difference between formulas (F test, $p > 0.05$).

Table II. Performance characteristics of "customized formulas" (mean ± SD)

Formula No.	*Error (%)*		*Error (gm)*	
I	−1.1 ± 12.2*	*	15 ± 409*	*
II	−0.9 ± 12.1		19 ± 409	
III	−0.9 ± 11.0		16 ± 394	
IV	−1.8 ± 11.5		−17 ± 396	
V	−0.9 ± 12.0		27 ± 406	
VI	−5.2 ± 12.6		−128 ± 432	
VII	−2.4 ± 13		−13 ± 415	

*No difference between formulas (F test, $p > 0.05$).

The formulas generated from the first 80 patients (the "training set") are as follows (their performance characteristics, when applied to the "test set," are presented in Table II):

I. (Warsof et al.'s variant)
$$\log_{10}(FW) = -2.579 + 0.267(BPD) + 0.048(AC) - 0.000340(BPD)^2(AC)$$

II. (Shepard et al.'s variant)
$$\log_{10}(FW) = -2.9944 + 0.313(BPD) + 0.0865(AC) - 0.00734(AC)(BPD)$$

III. (Hadlock et al.'s variant)
$$\log_{10}(FW) = -2.080 - 0.00638(AC)(FL) + 0.00265(BPD)^2 + 0.0623(AC) + 0.255(FL)$$

IV. $$FW = -3.457 + 0.0725(FL) + 0.122(AC) + 0.00333(FL)(AC) + 0.0168(BPD)^2$$

V. $$\log_{10}(FW) = -3.509 + 0.618(BPD) + 0.0262(AC) + 0.0645(FL) - 0.0323(BPD)^2 - 0.00109(FL)(AC)$$

VI. $$\log_{10}(FW) = -3.383 + 1.24\log_{10}(BPD) + 1.45\log_{10}(AC) + 0.607\log_{10}(FL)$$

VII. $$FW = 0.0544 - 0.00141(BPD)^3 + 0.00271(FL)(AD)^2$$

The variant formulas of Warsof et al., Shepard et al., and Hadlock et al. had smaller systematic errors and greater precision than their parent formulas, but the differences were minor and not statistically significant. As with current formulas, the variant formula of Hadlock et al. had the greatest precision (that is, the lowest standard deviation of 11.0%), besting the variants of Warsof et al. and Shepard et al. as well as all other formulas generated. None of the differences among formulas, however, was statistically significant ($p > 0.05$).

Table III. Fetal weight estimate versus birth weight

*Estimated fetal weight (gm)**	*Actual weight*			
	<4000 gm		*>4000 gm*	
	n	%	*n*	%
<4000	112	84	22	16
>4000	6	23	20	77

*By the Hadlock formula.

Table IV. Actual weight as a function of prenatal weight estimate in infants of diabetic mothers

*Estimated fetal weight (gm)**	*No. of fetuses*	*% Macrosomic*
<3500	96	7
3500-3999	39	39
4000-4499	19	74
>4500	7	86

*By the Hadlock formula.

We grouped cases according to fetal weight estimate by the Hadlock formula in order to determine the ability to diagnose or rule out macrosomia in the infant of a diabetic mother. The results are listed in Table III. A fetus with a weight estimate <4000 gm has a 16% chance of being macrosomic, whereas a fetus with an estimated weight >4000 gm is likely (77%) to be macrosomic. A further breakdown of our groups for narrower weight ranges is presented in Table IV.

Comment

The macrosomic infant of a diabetic mother is at increased risk for birth trauma secondary to shoulder dystocia or failed forceps delivery, among other problems. The incidence of shoulder dystocia in the general population is 0.5%. This increases to 31% in the macrosomic infant of a diabetic mother.[9] Accurate antenatal fetal weight prediction could therefore lead to a considerable reduction in perinatal morbidity in this group.

Weight prediction has been shown to be of limited accuracy in the general population, and our study has demonstrated even less accuracy in the diabetic population. Specifically, in the general population, conventional formulas have been shown to have broad 95% confidence ranges of 15% to 22%.[4] That is, in 5% of cases the estimated weight will be in error by approximately 20% or more. Our results demonstrate that the conventional formulas have even wider 95% confidence

ranges of 24% to 26% in infants of diabetic mothers (2 SD, based on Table I). Although differences among formulas were slight (and not statistically significant), the Hadlock formula involving BPD, AC, and FL showed a tendency to predict weight more accurately than the Warsof and Shepard formulas. "Customized" formulas, generated with use of a group of diabetic fetuses and evaluated on a second "test set," performed no better than the conventional formulas.

Previous studies have addressed the accuracy of sonographic prediction of fetal macrosomia in diabetic pregnancies.[10-14] The definition of macrosomia has not been standardized, with some authors using a relative weight criterion (≥90th percentile)[11, 12, 14] and others an absolute weight criterion (≥4000 gm).[10, 13] Elliott et al.[10] reported a sensitivity of 87% but a predictive value of only 61% in identifying fetuses with birth weights >4000 grams. Bracero et al.[11] showed a 79% sensitivity and 80% specificity in using abdominal diameter/femur length ratios to identify the large for gestational age (≥90th percentile) infants of diabetic mothers. When we examined the use of a similar ratio, the FL/AC ratio, we found a positive predictive value of only 36% to 43%, suggesting that it has limited clinical utility.[13]

Clinical management decisions regarding route of delivery should be based on many factors. One of these is the risk of birth trauma. The incidence of shoulder dystocia in macrosomic (≥4000 gm) infants of diabetic mothers has previously been shown to be significantly increased.[9] Our results demonstrate a high likelihood (77%) of macrosomia when the estimated weight is at least 4000 gm. These findings taken together, while not conclusive, suggest that cesarean section is the most prudent route of delivery when the estimated fetal weight is ≥4000 gm.

We conclude that: (1) current formulas are even less accurate at predicting actual fetal weight in the diabetic mother than in the general population; (2) they do, however, provide considerable guidance at diagnosing and excluding macrosomia and therefore aid in selecting the most appropriate mode of delivery; (3) there is no evidence to support the use of "customized" weight formulas over conventional formulas in diabetic women; (4) pending further study, the Hadlock formula tested here appears to be the method of choice for weight prediction in diabetic women.

Ureteral obstruction as a complication of the Burch colposuspension procedure: Case report

Gerald B. Applegate, M.D., Katherine M. Bass, M.D., and Carolyn J. Kubik, M.D.
Pittsburgh, Pennsylvania

Major complications of the Burch procedure for stress urinary incontinence are rare. Inadvertent kinking of the ureter during this procedure has been described only once previously in the literature. We present a second such case, hoping to draw attention to this rare but significant complication. (AM J OBSTET GYNECOL 1987;156:445.)

Key words: Stress incontinence, Burch procedure, ureteral obstruction

Suspension of the lateral portion of the upper vagina to Cooper's ligament has become an established technique to correct urinary stress incontinence. First described and performed by Burch[1] in 1961, the procedure has few major complications. Intraoperative damage to the ureter with subsequent obstruction has been described only once previously in the literature but can have serious consequences for the patient, and care must be taken to avoid such an occurrence.

Case report

A 46-year-old, gravida 9, para 8, abortions 1, black woman presented to the outpatient clinic at Magee-Womens Hospital because of involuntary loss of urine for the previous 5 years. She had had total abdominal hysterectomy and right salpingo-oophorectomy for benign disease 10 years before presentation. Pelvic examination revealed no cystocele or urethrocele and preoperative cystometric parameters were within normal limits. The patient was admitted and underwent a Burch colposuspension procedure. Three ligatures of No. 0 Vicryl suture were used bilaterally to suspend the vagina to Cooper's ligament under moderate tension, with approximately 1 cm of free space allowed between the ligament and the vagina. The space of Retzius was drained through a separate stab wound. Blood loss at the time of operation was minimal.

On the third postoperative day, the patient developed a fever to 38.4° C and left flank pain and maintained a low-grade fever during the next several days. Full workup including blood and urine cultures revealed no source of infection. An intravenous pyelogram showed left ureteral obstruction approximately 1 cm above the ureterovesical orifice. Eight days after the original procedure, the patient was taken back to the operating room where she underwent cystoscopy with attempted ureteral catheterization without success. At reexploration, cystotomy was performed and the left ureter was found to be kinked and deviated laterally by the vaginal sutures. These were removed bilaterally and both ureters were catheterized, the free ends being brought down through the urethra. An intraoperative retrograde pyelogram demonstrated correct catheter placement with no obstruction. The bladder was drained suprapubically. The ureteral catheters were removed on the third postoperative day and a repeat intravenous pyelogram just before discharge showed only limited narrowing of the distal left ureter with no obstruction. Three months after operation, the patient denied symptoms of urinary stress incontinence, and her only complaint was of mild suprapubic discomfort.

Comment

The problem of urinary stress incontinence in the woman has been extensively addressed in the literature. In properly selected patients, the Burch retropubic urethrovesical suspension procedure offers a better than 85% long-range cure rate for genuine urinary stress incontinence. Minor complications include bladder trauma and venous bleeding while major complications are infrequent. Only one previous case of ureteral obstruction during a Burch procedure has been reported,[2] also in a patient who had undergone previous abdominal hysterectomy. As in our patient, fibrosis and scarring of the paravesical tissue resulted in kinking of the ureter during colposuspension, with subsequent obstructive uropathy. Early recognition and correction of the problem prevented permanent kidney damage in both patients. This rare complication must be kept in mind when one is attempting Burch colposuspension in patients who have undergone previous pelvic operation.

Vaginal Gram stain as an immediate detector of group B streptococci in selected obstetric patients

Steven M. Feld, M.D., and John T. Harrigan, M.D.
New Brunswick, New Jersey

During a 19-month period selective vaginal Gram stain and culturing were performed prospectively in all women admitted to the delivery room at risk for low birth weight delivery secondary to preterm premature rupture of the membranes or for prolonged membrane rupture seconcary to term premature rupture of the membranes. Gram stain was performed and read immediately on admission. Cultures were also obtained simultaneously and sent for microbiologic evaluation. All women with Gram stains positive for gram-positive cocci were treated with intravenous ampicillin in the event of labor, unless vaginal culture results were already known and were negative for group B β-hemolytic streptococcus. A total of 72 women had samples taken, and 30 (41.7%) were positive for gram-positive cocci. Nine (30%) of these were subsequently positive for group B β-hemolytic streptococci by culture. There were no cultures positive for group B β-hemolytic streptococci in the Gram stain–negative group. Gram stain sensitivity was 100% for predicting the presence of group B β-hemolytic streptococci in the study population, and specificity was 66.7%. Selective vaginal Gram stain provides an effective and rapid screen for identifying the presence of group B β-hemolytic streptococci and allows for immediate institution of appropriate antibiotic therapy in the event of onset of labor before the availability of culture results. (Am J Obstet Gynecol 1987;156:446-8.)

Key words: Group B streptococci, Gram stain, gram-positive cocci, immediate detection

The two most common bacterial pathogens in the neonatal period are group B β-hemolytic streptococci and *Escherichia coli*, accounting for 70% of all systemic neonatal bacterial diseases.[1] More significant is the ascension of group B β-hemolytic streptococci as a major cause of life-threatening neonatal infection in the United States.[2, 3] An estimated 12,000 to 15,000 newborn infants per year will develop early onset disease, and mortality is at least 50%.[4]

Prevention of this disease in the neonate is a formidable task, as asymptomatic maternal vaginal colonization is common, ranging from 5% to 30% of pregnant women.[1, 5, 6] Vertical transmission at birth is high, occurring in 75% of exposed newborn infants.[7] Fortunately, the attack rate for group B β-hemolytic streptococci is much lower with 1% of colonized infants becoming septic, giving an incidence of 0.6 to 4 per 1000 live births.[5]

Studies attempting to identify and treat antepartum mothers colonized with group B β-hemolytic streptococci have been ineffective in reducing maternal colonization at delivery.[8, 9] Intrapartum screening is more effective in predicting pregnancies that result in neonatal infection,[10] and more recently intravenous ampicillin given intrapartum to pregnant women colonized with group B β-hemolytic streptococci has prevented transmission to the newborn infant.[11, 12]

Certain neonates are at greater risk for developing disease relating to early onset of group B β-hemolytic streptococci, most notably those of low birth weight and those born after prolonged membrane rupture.[2, 3, 7, 13] The attack rate for low birth weight infants is 7.3 times that for term infants,[3] and the mortality rate is at least doubled.[5] Such newborn infants may benefit from intrapartum ampicillin before birth.[13, 14]

Obstetric conditions on occasion may require rapid identification techniques for the presence of maternal vaginal group B β-hemolytic streptococci in order to make informed decisions about initiating intravenous ampicillin before delivery. At present 18 hours or more is required for reliable identification of group B β-hemolytic streptococci,[14, 15] often leading to unnecessary antibiotic therapy. This study examines the effectiveness of the vaginal Gram stain as a rapid and accurate detector of group B β-hemolytic streptococci.

Material and methods

The study population comprised all pregnant women admitted to the delivery room in St. Peter's Medical Center at risk for low birth weight delivery secondary to preterm premature rupture of the membranes or for prolonged membrane rupture secondary to term

premature rupture of the membranes. From November 1981 through June 1983, vaginal cultures and Gram stain were obtained simultaneously from all women who fulfilled the above requirements. Preterm pregnancies included all those that had not completed 37 weeks' gestation. Premature rupture of the membranes was defined as rupture of the membranes preceding the onset of labor by any amount of time.

Sterile speculum examination was performed immediately on admission to the delivery room. Two culture swabs were obtained from the outer one third of the vagina. In addition, a third swab was used to streak a slide, and this specimen was allowed to air dry. All specimens were then immediately transported for microbiologic examination. One specimen was inoculated directly into selective Todd-Hewitt broth medium (5% sheep red blood cells, 8 μg/ml of gentamicin sulfate, and 15 μg/ml of nalidixic acid). At 24 hours inoculates were subcultured onto blood agar. Confirmation of group B β-hemolytic streptococci was obtained with the CAMP test. The second swab was treated anaerobically.

The air-dried smear was used to prepare a Gram stain immediately in the following manner by one of three fellows in maternal-fetal medicine. The smear was heat-fixed and stained with Gentian violet for 1 minute. It was then washed in tap water, and Gram's iodine solution was applied for 1 minute. The smear was again washed in tap water and decolorized in 95% ethyl alcohol for 30 seconds. Once again it was washed in tap water and then counterstained for 20 seconds with safranin. As soon as the Gram stain was completed, it was examined microscopically. Any presence of gram-positive cocci in clumps, pairs, or chains or in an isolated instance was considered positive for group B β-hemolytic streptococci for the purposes of this study until culture results were available.

After sterile speculum examination, no further examinations were done in the study population unless labor occurred. Those women with preterm premature rupture of the membranes were managed conservatively. At the end of 1 week's hospitalization, if no signs of labor or chorioamnionitis existed, they were discharged. Those women with term premature rupture of the membranes were observed for 12 hours, and if labor had not ensued by then, intravenous oxytocin induction of labor was begun.

In the event of labor or induction of labor, if group B β-hemolytic streptococci was present by culture, 1 gm of ampicillin was given intravenously every 4 hours until delivery. If culture results were not yet available, decision for treatment was based solely on Gram stain results.

Once culture results were available, Gram stain and culture were matched for each woman in the study population. Degree of correlation between the two was reviewed.

Results

Vaginal Gram stain and culture were obtained in 72 women during the study period. A total of 61 (84.7%) were admitted for preterm premature rupture of the membranes, while 11 (15.3%) were admitted for term premature rupture of the membranes. A total of nine women had positive vaginal cultures for group B β-hemolytic streptococci, yielding a 12.5% colonization rate. This rate is consistent with the range of colonization reported in other populations.[1, 5, 6] Colonization rate in the preterm premature rupture of the membranes population was 11.5% (seven of 61), while the rate with term premature rupture of the membranes was slightly higher, at 18.2% (two of 11). Again both rates fall within the reported range.

Thirty of 72 Gram stains were positive for gram-positive cocci, giving an incidence of 41.7%. Of these 30, nine (30%) were subsequently positive for group B β-hemolytic streptococci by vaginal culture. Table I lists the various organisms isolated by culture in the Gram stain positive for gram-positive cocci population, with their respective percentages of total. Group B β-hemolytic streptococci was the largest subpopulation. Table II shows the relationship between Gram stain findings and group B β-hemolytic streptococci vaginal culture results. There were no vaginal cultures positive for group B β-hemolytic streptococci in the Gram stain negative for gram-positive cocci group.

All nine women with group B β-hemolytic streptococci by vaginal culture were accurately identified on admission to the delivery room by the Gram stain being

positive for gram-positive cocci. No woman subsequently had a positive culture for group B β-hemolytic streptococci if the initial Gram stain had been negative for gram-positive cocci. Gram stain sensitivity for predicting the presence of group B β-hemolytic streptococci vaginally was 100% for the study population. There were no false negative results. Gram stain specificity was 66.7%.

Comment

Early onset group B β-hemolytic streptococci infection can be life-threatening to the newborn infant. The disease course is often rapid and all too frequently leads to a fatal outcome. It is imperative that those neonates at risk be identified intrapartum so that mothers-to-be can be treated with antibiotics to minimize exposure during fetal passage through the birth canal, as suggested by prior studies.[11, 12, 14] This urgency must be balanced by the increased cost and risks that occur with widescale antibiotic therapy, since incidence of maternal carriage for group B β-hemolytic streptococci can be as high as 30%.[2, 14]

A population at high risk for developing early onset disease has been identified in several studies.[2, 3, 7, 10] Screening of those women admitted at risk for delivering low birth weight newborn infants or those born after prolonged membrane rupture would narrow the target population and eliminate the need for universal antepartum screening.

Even with such an approach, at least 18 hours is required from time of vaginal culture for accurate identification of maternal carriers of group B β-hemolytic streptococci.[14, 15] Many obstetric situations may occur that lead to delivery or active labor before group B β-hemolytic streptococci status is known. In preterm pregnancies with premature rupture of the membranes, more than 50% are in active labor within 24 hours, while 70% of pregnancies at term are in labor within 12 hours.[5]

The clinician is thus faced with the choice of treating such patients with antibiotics unnecessarily (if group B β-hemolytic streptococci cultures are subsequently negative) or not treating and exposing the neonate to potential risk (if group B β-hemolytic streptococci cultures are positive). Minkoff and Mead[14] have recently addressed this issue and suggest treating some patients unnecessarily to prevent intrapartum transmission in a population at high risk for early onset disease as described above. This approach is suggested until a simple, rapid, and accurate diagnostic test for group B β-hemolytic streptococci becomes available, thus eliminating the need for unnecessary antibiotics.

The vaginal Gram stain fulfills these requirements to a large extent. It is a simple and rapid test, as well as an inexpensive one, and has been used in the diagnosis of neonatal group B β-hemolytic streptococci disease with preparation of a smear of gastric aspirate.[6] The purpose of this study was to assess the accuracy of the Gram stain in diagnosing group B β-hemolytic streptococci. Of most importance would be its sensitivity, so that few maternal carriers of group B β-hemolytic streptococci are missed in screening a high-risk population.

A sensitivity of 100% in this small study population is promising. Further analyses in larger populations are needed to confirm these findings. If the sensitivity remains good, vaginal Gram stain will provide an easy and cost-effective screen for group B β-hemolytic streptococci.

C-reactive protein: A limited test for managing patients with preterm labor or preterm rupture of membranes?

J. M. Ernest, M.D., Melissa Swain, R.N., Steven M. Block, M.D., Lewis H. Nelson, M.D., Christos G. Hatjis, M.D., and Paul J. Meis, M.D.

Winston-Salem, North Carolina

C-reactive protein has been used to identify patients at high risk for infectious morbidity with preterm labor or preterm rupture of membranes. In this article we report on 104 patients with preterm labor symptoms (n = 45) or preterm rupture of the membranes (n = 59) and serial evaluations of C-reactive protein measured by latex agglutination and laser nephelometry. The simple, inexpensive latex method appears comparable to the laser method in predicting infectious morbidity and can be used clinically. Elevated C-reactive protein values before delivery predict infectious morbidity in only 8% to 29% of patients, and up to 18% of patients with serious infections may be misdiagnosed as having normal C-reactive protein values before delivery. (AM J OBSTET GYNECOL 1987;156:449-54.)

Key words: C-reactive protein, preterm labor, preterm rupture of membranes

Preterm labor and delivery remains the leading cause of perinatal morbidity and mortality today. A major problem associated with preterm labor is intra-amniotic infection, which may occur either before or after rupture of the fetal membranes.[1-4] While these intra-amniotic infections can lead to serious sequelae in both mother and infant, our ability to detect early amnionitis remains poor.

Several authors have recently evaluated the acute-phase reactant C-reactive protein as a potential marker of infectious morbidity in patients at risk for preterm delivery.[5-11]

The purpose of this paper is to report C-reactive protein levels and infectious morbidity in patients with preterm labor symptoms or preterm rupture of the membranes.

Methods and materials

Between August 1, 1983, and May 31, 1984, all patients between 26 and 34 weeks' gestation presenting to the Consolidated Obstetrical Service of Forsyth Memorial Hospital and Wake Forest University Medical Center with preterm rupture of the membranes (n = 114) or signs of preterm labor (n = 171) were considered eligible for inclusion in the study group. After obtaining informed consent as approved by the Clinical Research Practices Committee from 104 patients, each patient had a mean of 8.7 C-reactive protein levels measured (range = 1 to 32) before delivery for a total of 907 samples. Forty-five of the 104 patients had signs of preterm labor, which included uterine contractions, change in cervical dilatation or effacement, or both, while the remaining 59 patients had rupture of the membranes as documented by pH testing and "fern-ing" of vaginal fluid during a sterile speculum examination. Patients with preterm labor documented by uterine contractions and cervical changes were begun on a regimen of intravenous tocolytic agents and changed to oral tocolytic drugs per established protocols. If labor was successfully arrested, preterm labor patients were discharged home to continue oral tocolytics until 37 weeks' gestation. All preterm labor patients discharged undelivered were considered as not having amnionitis, and at subsequent delivery none had signs of amnionitis or neonatal infection. Five patients were admitted on two separate occasions and each admission was considered separately. Patients with documented preterm rupture of the membranes were managed expectantly in the hospital until delivery and were allowed to labor spontaneously unless amnionitis, fetal distress, or fetal lung maturity, documented by a lecithin/sphingomyelin ratio of ≥2:1 or the presence of phosphatidylglycerol in vaginally collected amniotic fluid, was noted, at which time delivery was facilitated by oxytocin induction or cesarean delivery. A total of 109 admissions of the 104 patients who consented to participate were studied.

C-reactive protein was measured daily by two parallel methods, latex agglutination and laser nephelometry.

Any maternal or neontal infection	109/25	Latex	76	44	29	86	2.457	0.11

Table II. Infectious morbidity and laser C-reactive protein >0.8 mg/dl any time before delivery

	No. of patients per no. of infections	*Test method*	*Sensitivity (%)*	*Specificity (%)*	*Positive predictive value (%)*	*Negative predictive value (%)*	χ^2	*p*
Maternal amnionitis	85/6	Laser	67	38	8	94	0.044	0.67
Maternal amnionitis and/or neonatal infection	85/10	Laser	60	37	11	88	0.034	0.66
Any maternal or neonatal infection	94/19	Laser	68	37	22	82	0.040	0.67

Latex agglutination (Rapitex, Calbiochem-Behring*) is a rapid antigen detection method that is reported as positive (>0.8 mg/dl) or negative (≤0.8 mg/dl) as determined by agglutination on an agitated slide of the serum (C-reactive protein antigen) and reagent (antibody to C-reactive protein). Laser nephelometry quantitatively determines C-reactive protein and reports values from 0.6 to 10 mg/dl. Normal nonpregnant values range from 0.08 to 0.8 mg/dl.[12] There is an excellent correlation between the latex and laser nephelometric C-reactive protein determinations (unpublished data). Neither method was used for patient management. Separate analyses of C-reactive protein values obtained within 12 hours before delivery and C-reactive protein values obtained at any time after hospitalization but before delivery were performed. Both latex (reported as positive or negative) and laser (positive considered to be >0.8 mg/dl and a separate analysis with positive >2.0 mg/dl) values were studied. The laser nephelometry values were chosen because >0.8 mg/dl correlates with a positive latex agglutination test and >2.0 mg/dl is a value reported in the literature as being predictive of infections morbidity.

Definition of infectious morbidity. After other sources of infection were excluded by careful physical examination, routine urinalysis, urine culture and sensitivity when indicated, and other indicated tests (chest x-ray film, for example) and after vaginal culture for group B β-hemolytic streptococci and *Neisseria gonorrhoeae*, amnionitis was considered present by documentation of the following: (1) maternal temperature >38° C (100.4° F) before delivery with any two of the following—white blood cell count >20,000/mm³ in the absence of steroid administration for at least 48 hours before white blood cell count determination, maternal or fetal tachycardia, uterine tenderness, or foul-smelling amniotic fluid; (2) pathogens isolated from the placenta at the time of cesarean delivery; (3) pathogens isolated from amniotic fluid obtained at amniocentesis.

Pathogens from the placenta or amniotic fluid included group B β-hemolytic streptococci, *Acinetobacter*, and anaerobes. Other maternal infections included urinary tract infections (>10^5 colonies per milliliter), recent conversion to positive VDRL test results, otitis media, bacterial pneumonia, and viral upper respiratory infection.

Neonatal congenital infection was diagnosed within 3 days of birth. Criteria for definite sepsis included clinical illness and positive blood cultures. Criteria for probable sepsis included at least two of these criteria: (1) clinical illness; (2) complete blood count with neutropenia or immature to total neutrophil ratio >0.20; (3) positive gastric aspirate, Gram stain, or culture; (4) positive placental culture; (5) foul odor.

Evidence of infection was not considered to be present if positive vaginal or placental cultures for common vaginal flora (for instance, group B streptococci or *Escherichia coli*) were reported after vaginal delivery. Histologic chorioamnionitis was not evaluated because of the uncertain correlation between that parameter and clinical infection.[2, 13]

*Behring Diagnostics, Division of American Hoechst Corporation, 10933 North Torrey Pines Road, La Jolla, CA 92037.

Table III. Infectious morbidity and laser C-reactive protein >2.0 mg/dl any time before delivery

	No. of patients per no. of infections	*Test method*	*Sensitivity (%)*	*Specificity (%)*	*Positive predictive value (%)*	*Negative predictive value (%)*	χ^2	*p*
Maternal amnionitis	85/6	Laser	60	64	10	96	0.420	0.52
Maternal amnionitis and/or neonatal infection	85/10	Laser	30	61	9	87	0.034	0.66
Any maternal or neonatal infection	94/19	Laser	47	61	24	82	0.184	0.65

The sensitivity, specificity, and positive and negative predictive values were determined for C-reactive protein levels in three separate clinical situations: (1) maternal amnionitis alone, (2) maternal amnionitis with or without neonatal infection, (3) maternal amnionitis or any other maternal infection with or without neonatal infection. The χ^2 analysis was used with $p < 0.05$ considered significant.

Results

A total of 27 infectious episodes were noted during the 109 admissions, including eight patients with amnionitis, seven with neonatal infection, and 12 with other maternal infections (eight with urinary tract infections and one each with recent positive VDRL test results, otitis media, bacterial pneumonia, and viral upper respiratory infection. Only two of the eight patients with amnionitis had concomitant neonatal sepsis.

Tables I through III give the sensitivity, specificity, and predictive values for infectious morbidity in patients with preterm labor or with preterm rupture of the membranes with the use of any positive C-reactive protein values at any time before delivery. In Table I C-reactive protein is measured by latex agglutination with values >0.8 mg/dl reported as positive, while Tables II and III report C-reactive protein measured by laser nephelometry with values >0.8 and 2.0 mg/dl, respectively, reported as positive. Sensitivity, specificity, and predictive values with a positive C-reactive protein value within 12 hours before delivery for the latex and laser measurement were also calculated and showed similar results to those of Tables I through III.

The negative predictive value of C-reactive protein measurements is much greater than the positive predictive value in all instances. In general, sensitivity was greater than specificity for most categories considered.

After other sources of infection were ruled out and when maternal amnionitis and neonatal infection only were considered, a positive C-reactive protein value at any time before delivery by either test method predicted infection 9% to 18% of the time. When only C-reactive protein values obtained within 12 hours before delivery were considered, the predictability was not improved and remained between 8% and 19%. These false positive C-reactive protein values, when quantitated by laser nephelometry, ranged from 2.1 to 9.8 mg/dl with no evidence of infection. False negative C-reactive protein values were less common but were present in 7% to 13% of patients with amnionitis or neonatal infection. These patients with "false normal" C-reactive protein values included a neonate with enterococcal sepsis, a neonate with group B streptococcal sepsis, and a patient whose placental cultures obtained at the time of cesarean section grew group B β-hemolytic streptococci.

Comment

Since 1980 seven articles have reported C-reactive protein values and infectious morbidity during pregnancy. Four reported on patients with premature rupture of the membranes,[5,7,8,10] one included patients with preterm labor and premature rupture of the membranes,[6] and two correlated C-reactive protein levels with outcome of tocolysis in patients in preterm labor.[9,11] A summary of these reports is presented in Table IV. A comparison of the sensitivity, specificity, and predictive values from previous studies with those of the present article is presented in Table V.

Six of the seven groups reported that C-reactive protein measurements are useful predictors of infectious morbidity, while Farb et al.[6] stated that C-reactive protein measurements are "not a specific or sensitive indicator of clinical or histologic amnionitis." The present study finds similarities with and differences from previous reports.

As in previous studies, the negative predicitve value of C-reactive protein is greater than the positive predictive value. In the present report, if all C-reactive protein values were negative before delivery, only 7% to 13% of patients would exhibit evidence of maternal amnionitis and/or neonatal infection. If one or more C-reactive protein values were positive before delivery, however, the test could no longer be used as a negative predictor, and only 9% to 18% of patients with one or more positive values would show evidence of maternal amnionitis and/or neonatal infection. This low positive predictive value contrasts to results in the majority of previous articles with reported positive predictive val-

Definition of infectious morbidity	*Comments*
Any of following present before delivery: Temperature ≥37.5° C, positive maternal or neonatal culture, histologic chorioamnionitis, elevation of white blood cell count to 50% over baseline value, >6 bands on differential, any toxic granulations	Excluded intracurrent illness such as SLE and RA; no mention of steroid use
Clinical: Temperature >37.5° C or white blood cell count rise ≥50% above admission level together with either uterine tenderness or fetal tachycardia; also used histologic criteria	C-reactive protein obtained every 12 hr until delivery; steroids given; "not specific or sensitive indicator of clinical or histologic chorioamnionitis"
Histologic chorioamnionitis; subgroups with temperature ≥38° C within 12 hr of delivery or positive endometrial-placental cultures	Compared C-reactive protein to white blood cell count, erythrocyte sedimentation rate, % bands
Temperature >100° F and other criteria "established by Gibbs, Koh, Garite, and others"	Steroids given; stated "prolonged uterine activity >6 hours" was cause of elevated C-reactive protein
Studied successful or failed tocolysis with positive C-reactive protein	Urinary tract infection not a confounding factor according to authors
Temperature ≥38° C or tender uterus or foul-smelling amniotic fluid and fetal tachycardia; also reviewed histologic chorioamnionitis	—
Studied successful or failed tocolysis and C-reactive protein	—

ues for amnionitis or neonatal infection of 50% to 100%.

There are several possible reasons for the varying results between the present study and previous studies. The present study uses a stricter definition of amnionitis than was used in earlier studies in an attempt to avoid placement of noninfected patients into the infected group. The present definition could therefore exclude some patients with early or subclinical infection. "Histologic chorioamnionitis" was not used to define infection in the present study since previous reports have noted its occurrence in many noninfected patients and its validity as a marker of true infection has been questioned. Fox,[14] for example, found some degree of histologic chorioamnionitis present in 24.4% of 1000 consecutively delivered placentas in Manchester, England. Driscoll[15] observed acute inflammation of amnion and chorion in 10.7% of 3600 cases and could not use placental inflammation to distinguish between infected and noninfected cases. More recently, Bobitt et al.[2] reported no correlation between histologic chorioamnionitis and the presence or absence of microorganisms in amniotic fluid, and Mortimer et al.[13] stated that "placental villitis is usually not an infective condition." White blood cell count elevations within 48 hours of maternal steroid administration were not used to define infectious morbidity since leukocytosis is commonly seen without infection after systemic steroid use. Disease incidence can affect the predictive accuracy of a test and should be examined when studies with different results are compared. The percent of patients with evidence of histologic chorioamnionitis in the previously reported studies ranged from 17% to 63% with a mean of 37% while the clinical chorioamnionitis rates were between 13% and 47% with a mean of 25%. The present study had comparable rates of overall infectious morbidity of 25% and amnionitis or neonatal infection rates of 12%. The differences in incidence between studies may explain slight variations in predictive value but should not account for the wide variation between positive predictive values between the present and previous reports.

In conclusion, an early simple marker of occult intraamniotic infection in patients at risk for infectious morbidity would be very useful in the management of certain high-risk obstetrics patients. Expectantly managed patients with premature rupture of the membranes as well as patients in preterm labor would benefit from additional parameters of infection that could be used in conjunction with the maternal temperature, maternal and fetal heart rates, uterine tenderness, and white blood cell count and differential report. In contrast to results of previous reports, a patient with all normal C-reactive protein values before delivery in whom other causes of infection have been ruled out may still have a 13% chance of developing maternal amnionitis or a neonatal infection while a positive (elevated) C-reactive protein value will predict amnionitis or neonatal infection only 9% to 18% of the time.

If C-reactive protein levels are to be used in the management of patients in preterm labor or with premature rupture of the membranes, the latex agglutination test is as reliable as the more expensive and complicated laser nephelometric determination. C-reactive protein values may be helpful if consistently normal (or negative), but significant maternal or neonatal infection may still occur in up to one of eight of those patients. Elevated C-reactive protein values predict infection in only one of five patients and are therefore inaccurate predictors of infectious morbidity.

Comparison of phospholipids in vaginal and amniocentesis specimens of patients with premature rupture of membranes

David C. Shaver, M.D., Joseph A. Spinnato, M.D., David Whybrew, M.S., W. Keith Williams, M.D., and Garland D. Anderson, M.D.

Memphis, Tennessee

Amniotic fluid was obtained from the vaginal pool and by transabdominal amniocentesis in 28 patients who were admitted to the hospital between 26 and 35 weeks' gestation with premature rupture of the membranes. Phospholipid profiles were obtained on all specimens with the use of high-performance liquid chromatography. The lecithin/sphingomyelin ratio, phosphatidylglycerol, phosphatidylinositol, phosphatidylethanolamine, phosphatidylserine, and lysolecithin were all analyzed to determine the effect of vaginal contamination. With the use of a paired *t* test, only lysolecithin was shown to be significantly affected by vaginal contamination ($p < 0.05$). As determined by high-performance liquid chromatography, evaluation of phospholipids in vaginal fluid of patients with premature rupture of the membranes appears to be an accurate and reliable method for predicting fetal lung maturity. (AM J OBSTET GYNECOL 1987; 156:454-7.)

Key words: Premature rupture of membranes, lecithin/sphingomyelin ratio, pulmonary phospholipids

Neonatal pulmonary performance is a major determinant of ultimate outcome for the prematurely delivered infant. Suggested management strategies for patients with premature labor have relied heavily on the presence or absence of fetal pulmonary maturity, as determined by assessment of amniotic fluid obtained through amniocentesis. However, amniocentesis for such purposes in patients with premature rupture of the membranes is possible in only 50% of cases.[1] Although transvaginally collected amniotic fluid has been used for management decisions in some series, the reliability of these determinations has been questioned. The purpose of this prospective study is to compare phospholipid measurements from amniotic fluid specimens obtained vaginally with those obtained transab-

dominally in patients with preterm premature rupture of the membranes.

Material and methods

Fluid collection. Approximately 100 patients who were admitted to the E. H. Crump Women's Hospital and Perinatal Center with the diagnosis of premature rupture of the membranes were evaluated for inclusion in the study. Only patients with gestational ages ranging from 26 to 35 weeks were considered. Following admission to the hospital, a sterile speculum examination was performed to confirm premature rupture of the membranes, and amniotic fluid was collected from the posterior fornix. Free-flowing fluid from the cervix was not required; in several cases only pooled vaginal fluid could be obtained. Ultrasonography was then performed, and if an adequate pocket of fluid was identified an amniocentesis was carried out under aseptic conditions, with real-time ultrasound guidance. If no site for amniocentesis could be identified, the patient was placed in the Trendelenburg position and reevaluated in several hours. If timely amniocentesis could not be performed, the patient was excluded. All vaginal and amniocentesis specimens were obtained within 12 hours of each other. Because of difficulty in obtaining both vaginal and amniocentesis fluid in each patient, 28 patients who fulfilled these criteria were enrolled in the study.

Instrumentation. All amniotic fluid phospholipid separations were carried out on a Hewlett-Packard Model 1084B high-performance liquid chromatograph equipped with a variable wavelength detector. The chromatographic separation was achieved with the use of a 5 cm, 40 μm Porasil (Supelco, Inc.) guard column followed with a 20 cm by 4.6 mm LiChrosorb 10 μm Diol column (Hewlett-Packard). The eluted phospholipids were quantitated by ultraviolet absorption at 203 nm and the detector response set at 0.0128 au/cm.

Analytical conditions. A linear gradient was run from 2.7% to 15% water in acetonitrile. The separation of the phospholipids was achieved at a flow rate of 1.2 ml/min. The solvent temperatures were maintained at 40° C, while the column temperature was 35° C. Integration of the peak areas was the means of quantitation.

Chromatographic analysis. Standard curves for each of the phospholipids of interest were determined by assaying 3, 5, 10, 15, and 20 μg amounts of each phospholipid in 5 μl quantities. Each of the phospholipid peaks was verified by thin-layer chromatography according to the technique of Hallman et al.[2] Amniotic fluid phospholipids were extracted by the procedure of Morrison et al.,[3] except that the amniotic fluid sam-

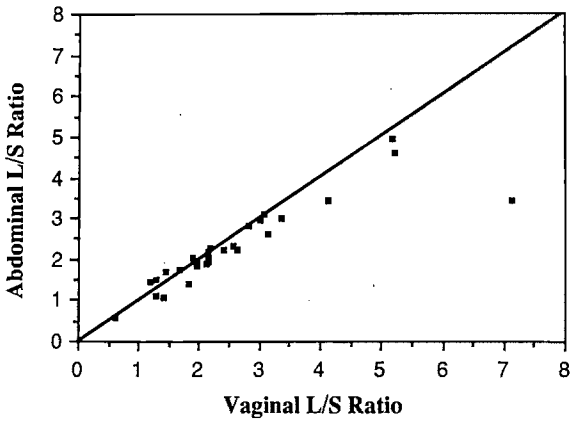

Fig. 1. Scatterplot showing the relationship between lecithin/sphingomyelin *(L/S)* ratios of vaginal and amniocentesis fluid.

ples were centrifuged at 1000 × g. The dried extracted material was dissolved in 30 μl of chloroform and then assayed with high-performance liquid chromatography.

Statistical methods. Statistical evaluations were performed with the use of the paired *t* test and correlation coefficient. A p value of <0.05 was considered statistically significant.

Results

In all 28 patients included in the study, at least 5 ml of both vaginal and amniocentesis fluid was obtained. None were contaminated with blood or meconium.

High-performance liquid chromatography. The lecithin/sphingomyelin ratios, presence or absence of phosphatidylglycerol, and gestational age at the time of sampling for each patient are shown in Table I. In 25 of 28 patients (89%), both vaginal and amniocentesis specimens were in agreement in regard to maturity ($\geq$2.0:1) or immaturity ($<$2.0:1) of lecithin/sphingomyelin ratios. In the three remaining patients (Patients 1, 5, and 9) the lecithin/sphingomyelin ratios were closely paired slightly above or below a ratio of 2 in each case. The lecithin/sphingomyelin ratios are represented graphically in Fig. 1. As can be seen, there is good correlation between the samples, with a correlation coefficient of 0.88. The mean lecithin/sphingomyelin ratio of amniocentesis fluid was 2.3:1 (±0.99), and the mean lecithin/sphingomyelin ratio of vaginal fluid was 2.56 (±1.41). Paired *t* test did not reveal a significant difference between the specimens ($p = 0.06$).

Phosphatidylglycerol was present in amniocentesis specimens of nine patients. All patients with positive test results for phosphatidylglycerol, with one exception (Patient 1, 30 weeks), were at $\geq$34 weeks' gestation. Each patient with amniocentesis specimens containing phosphatidylglycerol also had clearly detectable phosphatidylglycerol in vaginal fluid. The correlation coefficient for phosphatidylglycerol was 0.94, and paired *t* test demonstrated no significant difference between the two groups ($p > 0.2$).

Comparisons of phosphatidylinositol, phosphatidylethanolamine, phosphatidylserine, and lysolecithin were also done. Correlation coefficients and results of paired *t* test of all the phospholipids measured are noted in Table II. Lysolecithin was the only phospholipid that was demonstrated to be significantly affected by vaginal contamination.

Neonatal outcome. None of the infants in cases where either vaginal or amniocentesis fluid indicated fetal lung maturity (18 patients) experienced respiratory complications. In the 10 patients with immature lecithin/sphingomyelin ratios, four infants (40%) had respiratory complications. Two of these infants were diagnosed as having the respiratory insufficiency of prematurity, and one of them died (Patient 4). The other two carried a diagnosis of respiratory distress syndrome and one of these infants also died (Patient 24). The incidence of pulmonary complications is of limited significance, however, since tocolytics and steroids were administered to several patients, and delivery was delayed for one week in three patients.

Comment

Assessment of fetal lung maturity is usually included in the evaluation of patients in whom premature delivery is contemplated or in those who are felt to be at high risk for premature delivery. However, in virtually all studies on management of patients with premature rupture of the membranes, no assessment of fetal lung maturity is included. This is presumably due to an unwillingness to accept the reliability of such studies on fluid obtained vaginally. An exception to this is the presence of phosphatidylglycerol in vaginal fluid, which has been shown to be an accurate predictor of fetal lung maturity.[4, 5]

This reluctance to accept the accuracy of studies on fluid obtained vaginally apparently dates from early work done on fetal lung maturity. Although several reports since that time have disputed these conclusions, they remain entrenched in the literature and in management practices.

Most reports that have addressed the issue of vaginal contamination in studies of lung maturity have not included patients with premature rupture of the membranes. Instead, several approaches such as washings of the vagina or transcervical amniocentesis with subsequent amniotomy have been used. Additionally, nearly all patients who were evaluated were at term gestation, and therefore the incidence of immature lecithin/sphingomyelin ratios was quite low.

Several reports have indicated a good correlation of

Table II. Relationship between vaginal and amniocentesis specimens of amniotic fluid

Phospholipid	*Amniocentesis specimen (mean ± SD)*	*Vaginal specimen (mean ± SD)*	*Correlation coefficient (r)*	*Paired t test (p value)*
Lecithin/sphingomyelin	2.3 ± 0.987	2.56 ± 1.41	0.88	0.06
Phosphatidylglycerol	0.045 ± 0.098	0.049 ± 0.098	0.94	0.20
Phosphatidylinositol	0.199 ± 0.156	0.190 ± 0.186	0.69	>0.20
Phosphatidylethanolamine	0.362 ± 0.247	0.365 ± 0.203	0.89	>0.20
Phosphatidylserine	0.293 ± 0.199	0.292 ± 0.205	0.88	>0.20
Lysolecithin	0.08 ± 0.123	0.112 ± 0.139	0.83	<0.05

lecithin/sphingomyelin ratios in amniotic fluid before and after vaginal contamination. Sbarra et al.[6] demonstrated that lavage of the vagina did not affect the lecithin/sphingomyelin ratio and further showed that there was no detectable lecithin or sphingomyelin in washings of vaginal fluid. Similar findings regarding lecithin/sphingomyelin ratios were reported by Phillippe et al.[7] and Golde.[8]

Dombroski et al.[9] evaluated 27 patients at term with transvaginal amniocentesis and subsequent fluid collection after amniotomy. Although lecithin/sphingomyelin ratio and phosphatidylglycerol correlated well, they expressed concern because the vaginal lecithin/sphingomyelin ratio exceeded the amniocentesis result 22% of the time.

All of the patients included in this study were <36 weeks' gestation with premature rupture of the membranes and with a wide range of lecithin/sphingomyelin ratios demonstrated. As measured by high-performance liquid chromatography, there appears to be little effect of vaginal contamination on the phospholipids commonly used to assess fetal lung maturity. Although the difference between lecithin/sphingomyelin ratios did approach statistical significance ($p = 0.06$) because of a slightly higher mean lecithin/sphingomyelin ratio in the vaginal group, this had virtually no effect on the individual patients and should be of little clinical significance. In only one case (Patient 13) was there a marked discrepancy in lecithin/sphingomyelin ratios (3.42:1 versus 7.13:1), which would have no impact on management.

The present study confirmed the reliability of assessing vaginal fluid for phosphatidylglycerol. However, phosphatidylglycerol was present in a minority of patients (nine of 28, or 32%), which would be expected at the gestational ages that were represented. Therefore, the ability to use other parameters of fetal pulmonary maturity, such as lecithin/sphingomyelin ratio, assumes greater importance.

Confidence in the accuracy of pulmonary maturity studies of vaginally obtained amniotic fluid should have an impact on management of patients with premature rupture of the membranes. Decisions regarding subjects such as the use of tocolytics, administration of corticosteroids, or timing of induction of labor could all be made with more authority if the status of fetal lung maturity were known.

Acute *Haemophilus influenzae* chorioamnionitis associated with intact amniotic membranes

Hung N. Winn, M.D., and Charles C. Egley, M.D.
Peoria, Illinois

While *Haemophilus influenzae* infection commonly occurs in the age group 6 to 48 months, it uncommonly affects adults. A case of acute chorioamnionitis due to *Haemophilus influenzae* in the presence of intact fetal membranes is presented. The low incidence of maternal urogenital carriage, the high attack rate, and the virulence are discussed. (Am J Obstet Gynecol 1987;156:458-9.)

Key words: Chorioamnionitis, sepsis, antibiotics

Acute chorioamnionitis occasionally occurs in the presence of intact fetal membranes. Premature rupture of the membranes significantly increases the risk of acute amnionitis. While a number of organisms have been associated with chorioamnionitis, *Haemophilus influenzae* has been a rare isolate. Gibson and Williams[1] reported the first case of *Haemophilus influenzae* amnionitis associated with premature rupture of the membranes. Reviewing the obstetric literature, we believe this is the first report of *Haemophilus influenzae* causing acute amnionitis while the membranes are still intact.

Case report

The patient, a 25-year-old white married woman, gravida 4, para 3, was transferred to our hospital because of preterm labor at 22 weeks of gestation without ruptured membranes. The patient's prenatal course was remarkable for chills, diarrhea, and nausea for 3 days before admission. Uterine contractions started about 6 hours before the transfer. Tocolysis was initiated with intravenous ritodrine to avoid delivery during transportation. Shortly afterward, ritodrine was discontinued because the patient developed hypotension (systolic and diastolic pressures ranged from 80 to 90 and 30 to 40 torr, respectively), diaphoresis, and a decreased level of consciousness. She had no chest pain or dyspnea. She received a fluid challenge of 1000 ml of 5% dextrose in water and lactated Ringer's solution during transport. On admission to our hospital the patient was conscious and diaphoretic. She had a rectal temperature of 38.9° C and a blood pressure of 90/30 torr in a supine position. Examination revealed regular uterine contractions every 4 to 5 minutes, mild uterine tenderness, and copious purulent discharge from the cervix. Ferning test of the vaginal discharge was negative for amniotic fluid. A tentative diagnosis of sepsis and preterm labor secondary to acute amnionitis was made. Amniocentesis revealed many gram-negative bacilli. A chest roentgenogram showed a left lower lobe infiltration suggestive of pneumonia on admission. The patient was given intravenous ampicillin, clindamycin, and gentamicin. She also received intravenous dopamine infusion at a low dose (10 μg/kg/min) to maintain systolic blood pressure above 90 torr. As soon as her condition had been stabilized, the patient underwent a hysterotomy for delivery of the fetus since the cervix remained closed and thick. A live-born 400 gm male infant with Apgar scores of 1 and 5 at 1 and 5 minutes, respectively, was delivered. The infant died shortly afterward because of immaturity.

Quantitative cultures of amniotic fluid and blood for aerobes and anaerobes revealed *Haemophilus influenzae*, not type B, as a single pathogen, which was sensitive to ampicillin. Cleocin and gentamicin were discontinued on the second postoperative day. The patient was maintained on a regimen of intravenous ampicillin for 5 days and was discharged on a regimen of oral amoxicillin. Intravenous dopamine was discontinued when the patient was in the recovery room. The temperature returned to normal within 24 hours of admission and she remained afebrile until discharged. Her postoperative course was uneventful. A repeat chest roentgenogram showed a decrease in the lung infiltration 3 days later. Serum cold agglutinin and mycoplasma serologic tests were negative. The placental pathologic examination revealed acute chorioamnionitis and funisitis.

Comment

Haemophilus influenzae is a gram-negative, nonmotile aerobic bacillus that requires hematin and nicotinamide adenine dinucleotide or precursor for optimal growth. It is a major cause of meningitis in children from age 3 months to 3 to 6 years. In adults symptomatic infection, when it occurs, often presents as pneumonia, usu-

ally from nonencapsulated strains. However, infection due to *Haemophilus influenzae* is uncommon in adults. *Haemophilus influenzae* amnionitis in the presence of intact membranes is especially rare.

There are two possible mechanisms by which *Haemophilus influenzae* can enter the amniotic cavity: hematogenous dissemination from another source of infection or ascending assault from the cervix and vagina. Respiratory infections are important sources of hematogenous spread due to *Haemophilus influenzae* infection. Furthermore, *Haemophilus influenzae* can cause bacteremia even without localized infection. It is possible that our patient had pneumonia due to *Haemophilus influenzae* with subsequent bacteremia and hematogenous dissemination to the amniotic cavity.

Haemophilus influenzae can also enter the amniotic cavity by an ascending route from the vagina and cervix. The carriage rate of this organism in the female genital tract is very low.[2] On the other hand, *Haemophilus influenzae* appears to have a high attack rate and virulence associated with significant maternal and neonatal morbidity. Beargie[2] obtained two positive cultures for *Haemophilus influenzae* among 1083 routine vaginal cultures done on asymptomatic patients admitted to the labor ward. One of the two patients with positive vaginal cultures for *Haemophilus influenzae* developed acute amnionitis and neonatal sepsis.[2] Our patient and the one reported by Gibson and Williams[1] also developed moderate hypotension and high fever early in the disease process. It is possible, although unlikely, that our patient developed two separate diseases at the same time, acute amnionitis from ascending infection and left lower lobe pneumonia.

The drug of choice for *Haemophilus influenzae* is ampicillin. Occasionally, an ampicillin-resistant organism may be isolated, in which case chloramphenicol is the alternative.

In conclusion, since acute amnionitis due to *Haemophilus influenzae* is a rare event, a high index of suspicion is required to diagnose and initiate a timely and appropriate treatment to decrease maternal and neonatal morbidity. The usual triple antibiotic therapy (ampicillin, clindamycin, and gentamicin) remains an excellent choice for acute amnionitis, especially in cases where sepsis is also present. *Haemophilus influenzae* should be added to the list of potential pathogens that can cause acute amnionitis even in the presence of intact membranes. Routine screening for this organism does not seem to be cost-effective at this time in view of the very low carriage rate.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Maternal serum α-fetoprotein, age, and Down syndrome risk

Glenn E. Palomaki, B.S., and James E. Haddow, M.D.
Scarborough, Maine

Before the discovery that an association existed between low maternal serum α-fetoprotein levels and Down syndrome, the ability to detect Down syndrome pregnancies was limited to women aged ≥35, whose individual risks were sufficiently high (≥1:270 in the second trimester) to justify offering amniocentesis. If such women were to opt for that procedure, about 20% of all cases of Down syndrome could be detected. It is now possible to identify an additional 20% of all Down syndrome pregnancies in women under age 35, with the use of a screening process that combines a woman's maternal serum α-fetoprotein level and her age. We present a method whereby a woman's individual odds for Down syndrome can be calculated by combining the maternal serum α-fetoprotein measurement with her age, on the basis of published age-related Down syndrome risk data and on maternal serum α-fetoprotein distributions for unaffected and Down syndrome pregnancies. These individual odds calculations provide the basis both for establishing maternal serum α-fetoprotein/Down syndrome screening cutoffs and for counseling. (AM J OBSTET GYNECOL 1987;156:460-3.)

Key words: Down syndrome, maternal serum α-fetoprotein, maternal age, odds, screening

The association between low maternal serum α-fetoprotein levels and Down syndrome has been thoroughly documented.[1-9] Maternal serum α-fetoprotein has been proposed as a screening test for Down syndrome risk,[2,5] and one prospective study has been published that demonstrates the feasibility of such screening.[10] In this paper we describe a method for calculating a woman's individual odds for carrying a Down syndrome pregnancy that takes both her MSAFP level and age into account. Attention has been called to the need for odds tables that can be derived from this method for use by health professionals such as obstetricians and genetic counselors.[11]

Background data necessary for the method

Down syndrome risk estimation by maternal age alone. Table I gives rates of Down syndrome births by maternal age from three sources as reported by Hook,[12] along with the mean rate and the resulting Down syndrome odds at term and midtrimester. The midtrimester odds are based on estimated spontaneous Down syndrome fetal losses of 29% between the second trimester and term.[13]

Distributions of maternal serum α-fetoprotein multiples of the median for unaffected singleton and Down syndrome pregnancies. Fig. 1 shows distributions of the maternal serum α-fetoprotein multiples of the median for both Down syndrome and unaffected singleton pregnancies. Both of these populations fit a log Gaussian distribution[1,2,14]; their log means and standard deviations are estimated from published medians and interquartile ranges.[2] The unaffected singleton distribution has been modified to approximate a population whose dates have been confirmed by sonographic biparietal diameter measurements.[15]

Method

Deriving an individual woman's likelihood ratio for Down syndrome on the basis of maternal serum α-fetoprotein multiples of the median. For an individual woman, the likelihood ratio for a Down syndrome pregnancy versus an unaffected singleton pregnancy can be estimated by first locating the maternal serum α-fetoprotein multiple of the median on the horizontal scale in Fig. 1 and then measuring the vertical distance from that point on the baseline to the Down syndrome and unaffected singleton curves. The likelihood ratio is the distance to the Down syndrome curve divided by the distance to the unaffected singleton curve. For example, the *dashed vertical line* in Fig. 1 indicates a maternal serum α-fetoprotein test result of 0.50 multiple of the median. The distance to the Down syndrome curve is 2.37 times greater than to the unaffected curve. Thus the woman's odds of carrying a Down syndrome fetus are found to be 2.37 times greater than before the maternal serum α-fetoprotein test result was known. The formula for calculating the height (Y) of a Gaussian curve at a given position on the baseline (X is $\log_{10}$ multiple of the median) is expressed in the following equation:

$$Y = \frac{1}{\sqrt{2\pi}\, s} e^{\frac{-(X-u)^2}{2s^2}}$$

*To find the likelihood ratio associated with an individual woman's maternal serum α-fetoprotein multiple of the median (for example, 0.50), identify the first significant digit (5) in the left-hand column and match with the second significant digit (0) located in the top row. The likelihood ratio for this example is 2.37.

where u is the mean of a population and s is the associated standard deviation. Table II displays likelihood ratios for Down syndrome after maternal serum α-fetoprotein testing as derived from the formula, in increments of 0.01 from 0.35 to 1.0 multiple of the median and in increments of 0.1 from 1.0 to 1.9 multiples of the median.

Estimating an individual woman's odds for Down syndrome, on the basis of age and maternal serum α-fetoprotein multiples of the median. Individualized odds can be assigned by combining the maternal age odds in Table I with the likelihood ratios in Table II. For example, a 32-year-old woman with a maternal serum α-fetoprotein multiple of the median of 0.50 is first assigned a maternal age odds in the second trimester of 1:563. Then this odds estimate is multiplied by

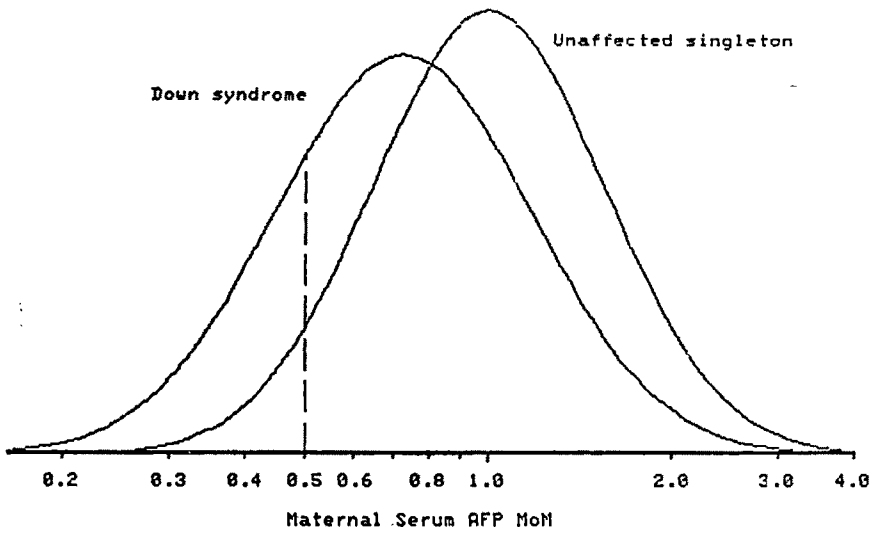

Fig. 1. Plot of the log Gaussian distributions of Down syndrome pregnancies (mean −0.14, SD 0.21) and unaffected singleton pregnancies with ultrasound dating (mean 0.00, SD 0.19).

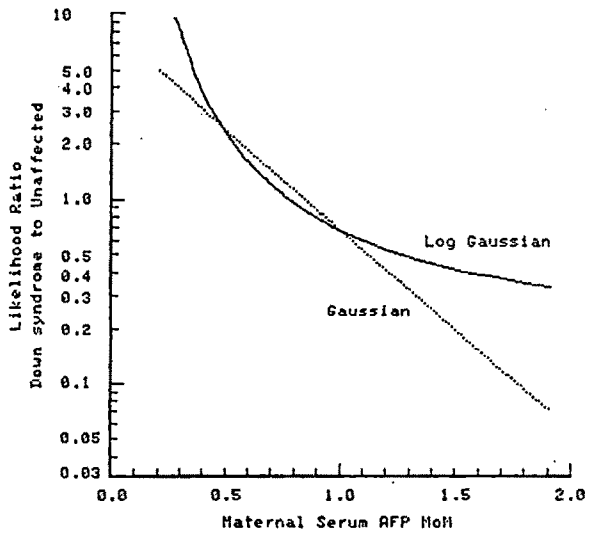

Fig. 2. Plot of the likelihood ratio of Down syndrome versus unaffected singleton pregnancy based on the log Gaussian model and the Gaussian model proposed by Baumgarten.

the likelihood ratio (2.37) associated with the maternal serum α-fetoprotein result, giving a combined odds of 2.37:563 or 1:238.

Comment

Means and standard deviations of the Down syndrome and unaffected singleton distributions have been estimated in this paper from published reports. As more data accumulate, better estimates may appear, and the odds table may need to be updated accordingly. However, the method of odds calculations will remain applicable.

Baumgarten[16] has suggested a method for estimating a woman's individual odds of carrying a Down syndrome fetus based on Gaussian rather than log Gaussian distributions for both the Down syndrome and unaffected singleton populations; in his method, distributions are also assigned identical standard deviations. His method and the standard method described here give similar likelihood ratios between 0.50 and 1.1 multiple of the median (Fig. 2), but they differ at lower and higher multiples of the median. For example, at 1.5 multiples of the median, the likelihood ratio according to the standard method is 0.45, whereas for the method suggested by Baumgarten it is 0.21. Because distributions for the two populations are known to be log Gaussian, risk estimates in the present paper are more likely to be correct.

The maternal serum α-fetoprotein multiple of the median is derived from a combination of gestational age estimation, the maternal serum α-fetoprotein measurement itself, and the laboratory's reference values (medians). As a refinement, the maternal serum α-fetoprotein multiple of the median can be corrected for maternal weight.[17] In our experience, when gestational dates have been calculated from the last menstrual period, about 75% of the maternal serum α-fetoprotein values <0.25 multiple of the median and 50% of the values between 0.25 and 0.50 multiple of the median are associated with overestimated gestational age. For that reason, last menstrual period estimates need to be confirmed by ultrasound before a final risk estimate can be made. Assay performance at the low end of the maternal serum α-fetoprotein range can be a problem[18] because maternal serum α-fetoprotein assays for pregnancy screening were originally optimized in the higher range for neural tube defect identification. Improperly

established maternal serum α-fetoprotein medians can also contribute substantially to error in Down syndrome odds assignment.

At present, pregnant women in the United States aged 35 years and older are offered amniocentesis for Down syndrome detection as part of routine prenatal care. This group of women has a second-trimester Down syndrome risk of at least 1:270 (Table I), and if all these women were to opt for amniocentesis, approximately 20% of all Down syndrome pregnancies could be detected. The association between maternal serum α-fetoprotein and Down syndrome provides an opportunity to define a group of younger pregnant women with Down syndrome risk equivalent to that of women 35 years of age and older. While low maternal serum α-fetoprotein levels are not strongly related to Down syndrome risk, approximately 20% of all cases can be identified in women under the age of 35 by the approach described here, thus offering the potential to double the number of Down syndrome cases detected while, at the same time, proportionately increasing the number of amniocenteses.

Delivery of fertility control services by male and female obstetrician-gynecologists

Carol S. Weisman, Ph.D., Constance A. Nathanson, Ph.D., Martha Ann Teitelbaum, M.P.H., Ph.D., Gary A. Chase, Ph.D., and Theodore M. King, M.D., Ph.D.
Baltimore, Maryland

Sex differences in the delivery of fertility control services were explored in a national survey of 1420 recently trained obstetrician-gynecologists in active practice. Women were found to be more likely than men to provide abortion services but less likely than men to provide amniocentesis and certain infertility services. Women were found to contribute less than their proportionate share of two services for which volume was measured: artificial inseminations and sterilizations. Physician gender, however, was a less important predictor of volume of sterilizations delivered than were a set of practice-related variables. Overall our findings suggest that the increased representation of women among obstetrician-gynecologists could influence the delivery of a few specific services. (Am J Obstet Gynecol 1987;156:464-9.)

Key words: Fertility control, women physicians, sterilization

This study was undertaken to explore how the increasing number of women entering practice in obstetrics-gynecology is likely to affect the delivery of fertility control services. A previous study of residents in obstetrics-gynecology in 1981 showed that women are more likely than men to support abortion, to approve of contraceptive services to 13- or 14-year-olds without parental consent, and to be interested in health education for women.[1] A recent survey by the American College of Obstetricians and Gynecologists[2] found that women obstetrician-gynecologists were more likely than men to report that abortions are justified under some circumstances. These findings suggest that female physicians might be more likely than men to provide these services, might provide them in a more supportive or empathetic manner, or might give greater attention to the cognitive aspects of fertility control. On the other hand, some have suggested that women will provide smaller numbers of surgical procedures, as compared with men.[3] We conducted a national survey of recently trained obstetrician-gynecologists to determine whether there are discernible sex differences in the number and types of fertility control services provided to patients. In this study, fertility control services include contraceptive services, abortion services, and diagnosis and treatment of infertility. In addition, services include specific procedures as well as counseling and referrals.

Methods

Data for this analysis are from a 1984 national survey of obstetrician-gynecologists consisting of a telephone interview and a self-administered questionnaire mailed to respondents to the interview. The target population consisted of all men and women who had graduated from medical school between 1974 and 1979 (the period of greatest increase in the number of women entering the specialty), who had completed residency training in obstetrics-gynecology, and who were in active practice at the time of the survey. The sampling frame selected was the membership roster of the American College of Obstetricians and Gynecologists, since this was the most efficient way of identifying physicians formally trained in obstetrics-gynecology. To assess whether the ACOG sampling frame adequately covered the target population, we conducted a survey of a sample of 200 physicians who had completed residency programs in 1983; using last-known addresses supplied by the residency programs, we traced the physicians and telephoned them to determine their ACOG membership status and current activity status in the profession. We found that 68% were ACOG members as of 8 months after residency and that there was no sex difference in membership rates. Further, nonmembers and members did not differ significantly with regard to activity status or type of practice arrangement. We

concluded that the ACOG sampling frame was appropriate for our purposes and did not introduce a sex bias.

The sample selected from the ACOG roster consisted of 100% of women who had graduated from medical school between 1974 and 1979 and a 28% systematic sample of comparable men: 930 men and 930 women were selected in this way. Subjects were then contacted by telephone, invited to participate in the study, and screened for eligibility on two additional criteria: completion of residency training in obstetrics-gynecology and current active practice. Fifteen subjects could not be located, and 253 refused to participate. Of the remaining subjects, 172 (9% of the original sample) were ineligible, primarily because they were still in full-time residency or postresidency training; only eight subjects (three men and five women) were "inactive" (neither in training nor in practice). There were no sex differences in reasons for ineligibility.

Eighty-four percent of the adjusted sample (original sample minus the ineligibles) completed the telephone interview (N = 1420). Among those interviewed, 84% then completed the mailed questionnaire. These are high response rates for a physician survey, and there were no sex differences in response rates to either instrument.

Respondents were located in all 50 states and had been in practice an average of 3 years at the time of our survey. The types of practice arrangements in which the respondents worked, their hours of work, and their numbers of encounters with patients have been described in a previous publication.[4]

Data reported in this paper include which fertility control services were provided by the physicians in any of the settings in which they practiced and, for selected services, the volume (number of units of the procedure) provided during the last year of the physician's practice. These data were obtained in the telephone interview, and physicians were instructed to give their best estimates for the volume figures. Self-reported volume

data should be viewed as estimates subject to possible rounding error and recall problems. It should be noted, however, that respondents answered the questions on volume with little difficulty; fewer than 10 respondents per question declined to report volume data. Furthermore, our findings regarding percentages of physicians providing certain services and average volume of certain services (for instance, sterilizations) are quite similar to those found in a recent survey of provision of fertility control services by a sample of private office-based obstetrician-gynecologists.[5, 6] Sex differences were not investigated in that survey.

Results

More than 90% of both men and women reported that their principal professional activity was direct patient care, and only two respondents provided no direct patient care. Only one woman and two men reported that they were not providing any fertility-control services in their practices, and 23% of men and 30% of women reported that "all or most" of their patient encounters in a typical workweek involved fertility control services.

Sixteen types of fertility control services are displayed in Table I, with proportions of men and women who reported that they had "personally delivered" any of these services during the last year of their practices and, if not, that they had referred patients elsewhere for the services. Virtually all men and all women reported that they provided contraceptive counseling-referral, prescriptions for oral contraceptives, diaphragms, sterilizations for contraceptive purposes, and infertility counseling-referral. These services appear to represent a core of fertility control services provided by the physicians in this sample. The services provided by the fewest respondents (in vitro fertilizations or implantations and ovum transplants) are still relatively new technologies.

There are few substantial sex differences in Table I. Women were significantly more likely than men to provide abortion counseling-referral and first-trimester abortions. If first- and second-trimester abortions are combined, 50.5% of women and 42.9% of men provided any abortions, a small but statistically significant sex difference. (In another publication we investigated the reasons why women are more likely to provide abortions, and we found that the major reason is that women have fewer ethical reservations than men about performing abortions under a variety of circumstances.[7]) Men were significantly more likely than women to provide amniocentesis, infertility testing, infertility drugs or treatment, and artificial insemination. The largest sex difference in the table occurs for amniocentesis, which was provided by 70% of women and 83% of men. This difference is not explained by subspecialty training or by access to a hospital that provides amniocentesis.

In Table II, data are presented on the volume of selected fertility control services reported for the last year of practice. (Data on volume were obtained for six services, but the numbers of respondents providing in vitro fertilizations and ovum transplants were too small for analysis.) As shown in the left-hand side of Table II, the tendency was for men to provide more units of each service than women; however, the sex difference is significant only for sterilizations (with men providing an average of 11.2 more sterilizations during the year), due to the smaller within-sex range for sterilizations.

does not, however, address the question of whether women are contributing to the overall volume of fertility control services in proportion to their representation in the target population of physicians. To answer this question, we used standard formulas for estimating population totals from a stratified sample.[8] The total number of procedures performed by the target population was estimated by extrapolating from the rates found in the sample and allowing for potential ineligibility among nonsampled members of the target population. The number of procedures provided by women was then divided by the estimated total number of procedures to get the estimated percentage of services provided by women. This figure was compared, in turn, to the estimated overall proportion of women in the target population (21.3%), with the use of an ad hoc interval estimate. (The interval estimate was constructed by computing the sample variance of the total number of procedures performed by men and disregarding the negligible sampling error in women.) When the estimated proportion of services provided by women differed by >2 SE from the 21.3% that women represent of the target population, the difference was considered significant.

As demonstrated in the right-hand side of Table II, women provided a proportionate share of the total number of abortions as the result of two opposing trends: their higher likelihood of providing the service offsets their tendency to provide a somewhat lower volume of abortions. However, women provided less than their proportionate share of sterilizations and artificial inseminations. In the case of artificial insemination (the largest discrepancy), this is because women are less likely both to provide the service and to perform a higher volume; in the case of sterilizations, women and men are equally likely to provide the service, but women perform fewer procedures. [For comparison purposes, we also found that, whereas 98% of men and 97% of women delivered babies during the last year of practice, women contributed less than their proportionate share of deliveries (17.2% of all deliveries) and provided an average of 35 fewer deliveries than men during the year.]

One possible explanation for women's lower volume of service provision was the fact that, at the time of our survey, the women had been in practice an average of nearly 1 year less than the men, because the women were concentrated in the more recent medical school graduation classes. To see whether less time in practice accounted for women's lower volume of service provision, we examined the volume of the specific services by number of years in practice. We found that the only fertility control service for which volume and years in practice were linearly associated was sterilizations and

that this association held for men but not for women. Women's volume of sterilizations maintained a fairly stable pattern and was uniformly lower than that of men, regardless of time in practice. (For comparison purposes, we found that both men and women increased their volume of deliveries with more years in practice, but women provided fewer deliveries than men at each level of practice experience.)

Since sterilization is now the leading form of contraception in the United States[9] and obstetrician-gynecologists are major providers of female sterilization services,[6] the finding that female physicians provide a slightly smaller than expected proportion of sterilizations was investigated further. In a multiple regression analysis, we explored whether a number of practice-related variables on which men and women were known to differ might account for the observed sex difference in volume of sterilizations provided (Table III). The standardized partial regression coefficients may be interpreted as the effect of the given variable, after all other variables have been taken into account, and as an indication of the relative strength of this variable as a predictor. When the number of sterilizations performed was regressed on physician's gender alone, the standardized partial regression coefficient was -0.20 ($p < 0.05$), whereas the coefficient for sex when the covariables were included (Table III) was reduced to -0.11 ($p < 0.05$).

The strongest predictor of sterilization volume was the physician's number of patient encounters per week: physicians treating more patients per week provided more sterilizations during the last year. This may be contrasted with the findings in our previous analysis of abortion performance; in that analysis, neither number of encounters nor number of hours worked by the physician predicted abortion volume.[7]

Other predictors of sterilization volume that were stronger than gender are practicing primarily in a multispecialty group (in this study, both men and women who practiced primarily in multispecialty groups provided larger numbers of sterilizations than those in other practice types); practicing in the north central or southern states (both men and women practicing in the northeast and west provided fewer sterilizations than those practicing in other regions); being in practice longer; working more hours per week; and practicing in a nonurban area (outside a large city or its suburb). With the exception of their greater likelihood of practicing in multispecialty groups, women tend to be in practice situations less conducive to high-volume sterilization services.

Attitudes relevant to provision of sterilization services were also measured in the survey. While women were significantly more likely then men to be supportive of greater patient decision power in the matter of sterilization, attitudes were not found to be associated with number of sterilizations performed. Attitudes therefore could not account for the residual sex difference in sterilization volume.

Comment

The number of sex differences in delivery of fertility control services is far outnumbered by the number of similarities in the practices of men and women in this study, and the magnitude of observed sex differences is not large. However, if the patterns established by these younger physicians hold, the increasing proportion of women in obstetrics-gynecology could have some influence on delivery of a few specific services. For instance, since women were more likely than men to provide abortions, the supply of physicians providing abortions would be expected to increase as the proportion of women in practice increases. On the other hand, the increasing proportion of women would reduce the supply of providers of amniocentesis and artificial insemination. Finally, women could contribute to a slight decline in the overall volume of sterilizations. Whether this would result in unmet consumer demand for sterilizations cannot be answered in this study.

The findings with regard to sterilizations are consistent with previous studies showing that female physicians in general tend to work fewer hours per week and have fewer patient encounters than their male colleagues.[10-12] However, the magnitude of the observed sex difference in volume is not large, and this could reflect the fact that the gap between the productivity levels of men and women physicians in general has narrowed.[13, 14] In addition, a previous paper reported that sex differences in total practice hours and in number of patient encounters per week were confined to the subgroup of the sample who were married and had children; thus, to the extent that lower volume of some services is a function of overall practice volume, the lower volume of services provided by women could be a function of the childbearing stage of the life cycle and might disappear as women age.[4]

Alternatively, the lower volume for women of some procedures could be due to a tendency by other physicians to discriminate against female physicians when referring patients for such procedures or by patients to discriminate against female physicians when seeking a provider to perform a surgical procedure such as a sterilization. Since there is evidence that women's preference for a female obstetrician-gynecologist increases with experience with a female physician,[15] effects of discrimination would be expected to diminish as more patients are served by female physicians.

A limitation of the survey approach is that it focuses on self-reported practice behaviors of physicians, and no data are available on the nature of physician-patient

interactions, quality of care provided, or patient satisfaction with care received. Therefore it cannot be discerned from these data whether the increasing proportion of women will affect these other aspects of delivery of fertility control services.

Three-contrasts method: An ultrasound technique for monitoring transcervical operations

Bao-Liang Lin, M.D., Yoshiyuki Iwata, M.D., Naohiko Miyamoto, M.D., and Shigeru Hayashi, M.D.

Kawasaki, Japan

The "three-contrasts method" of ultrasonography is designed to monitor transcervical operations for submucous uterine myomas and uterine septa when a pediatric urologic resectoscope is used. This monitoring method has proved more effective than concomitant laparoscopy. The pediatric resectoscope can also be used efficiently for diagnostic and therapeutic purposes without dilating the cervical canal. (AM J OBSTET GYNECOL 1987;156:469-72.)

Key words: Hysteroscopy, ultrasound, ultrasonography

It has previously been reported that transcervical resection of submucous uterine myomas and uterine septa can be performed by use of a resectoscope or an operating hysteroscope. To prevent uterine perforation, these operations have always been monitored by concomitant laparoscopy. When laparoscopy is being used, it is difficult to take precautions against perforation of the posterior uterine wall. In this paper we report the results of a new "three-contrasts method" of ultrasonography to monitor the transcervical resection of submucous uterine myomas and uterine septa. The three contrasts are derived from ultrasonographic examination of (1) a full urinary bladder, (2) fluid in the cul-de-sac, and (3) fluid in the uterine cavity or the inserted resectoscope. With this method a clear outline of the uterine wall and submucous myoma can be dis-

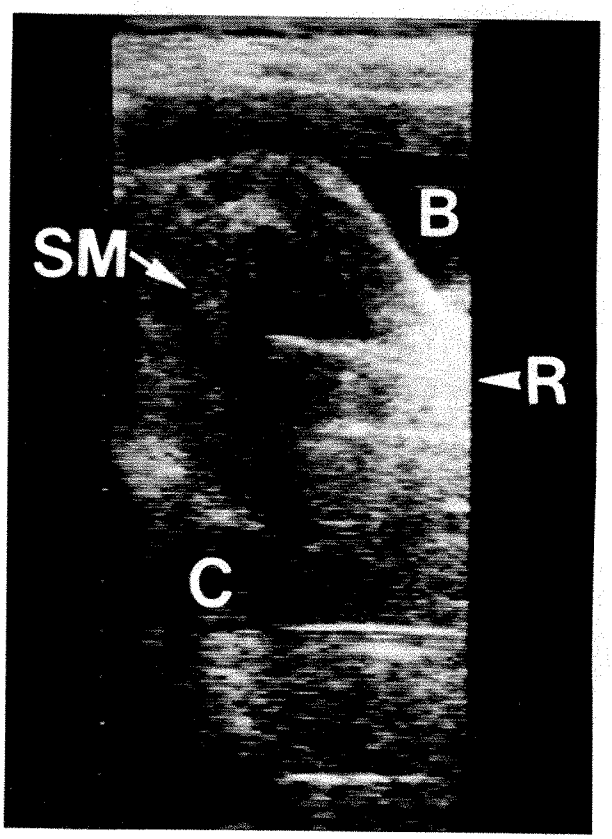

Fig. 2. Longitudinal section showing the resectoscope in the distended uterine cavity and the submucous myoma in front of the tip of the scope. *B* = Urinary bladder; *C* = cul-de-sac; *R* = resectoscope; *SM* = submucous myoma.

cerned, and injury to the uterine wall, resulting from overcutting of the scope, is prevented.

Material and methods

With the use of hysteroscopy six patients with complaints of menorrhagia and metrorrhagia were diagnosed as having submucous uterine myoma. Five were pedunculate in type and one was sessile. Menorrhagia was so severe in these patients that they all needed to use more than eight pads or tampons per day. Hemoglobin counts before iron therapy ranged from 4.7 to 10.6 gm/dl. Two other patients who complained of sterility were diagnosed (by means of hysterosalpingogram, hysteroscopy, and laparoscopy) as having uterine septa. All eight of these patients underwent transcervical operation with the use of a pediatric urologic resectoscope and ultrasound monitoring. Patients chosen for transcervical removal of submucous uterine myomas were selected according to the following criteria: (1) severe menorrhagia and/or intractable metrorrhagia, (2) uterus smaller than 9 weeks' gestational size, (3) submucous uterine myoma ≤30 mm in diameter, (4) no existence or suspicion of malignancy or premalignancy of the uterus. Diagnostic hysteroscopy was performed at our clinic with the use of a hysteroscope with an external sheath 4 mm in diameter (Olympus Optical Co.) without anesthesia or cervical dilation. After the diagnosis, all the patients underwent operative evaluation consisting of electrocardiogram, chest x-ray film, and evaluation of liver and renal function. The patient was admitted for transcervical operation when the menstrual period was over.

The night before operation, a balloon catheter was inserted in the cervical canal; the catheter was removed the next morning to facilitate insertion of the resectoscope. A completely cleansing enema was given before operation. All transcervical resection procedures were performed with the patient under general anesthesia. An intravenous indwelling catheter was inserted through the umbilicus into the abdominal cavity. This was connected, through an intravenous infusion set, to a 500 ml bottle of lactated Ringer's solution. Intra-abdominal infusion was then started. The patient was placed in Fowler's position to allow the infused fluid to accumulate in the cul-de-sac. At the same time about 200 ml of normal saline solution was introduced into

the urinary bladder through a balloon catheter. The catheter was retained throughout the operation in order to adjust the amount of fluid in the urinary bladder. An assistant then placed the transducer of a sonograph (SAL-35A, Toshiba Medical Systems Co.) in a longitudinal position in order to obtain a clear outline of the uterus, which was derived by checking the amounts of infused fluid in the cul-de-sac and urinary bladder.

A pediatric urologic resectoscope with an external sheath 4.5 mm in diameter (Olympus Optical Co.) was inserted into the uterine cavity through the cervical canal to reevaluate the status of submucous uterine myoma and uterine septum. Simultaneously, by moving the resectoscope in the distended uterine wall, the anatomic correlation of the uterine wall, submucous uterine myoma, uterine septum, and loop of the resectoscope was confirmed by means of ultrasonography (Figs. 1 and 2). The loop of the resectoscope, guided by the ultrasound, is set in the correct position for the cutting and coagulation process.

Cutting procedures were performed as follows: The loop of the resectoscope was placed on the farther side of the target and was drawn toward the objective lens of the scope. We tried to avoid shaving off a large mass while moving the cutting loop. The coagulation current was applied whenever hemostasis was required. When the cutting process was completed and the cutting site reached the normal uterine wall, the position of the resectoscope was carefully checked with ultrasound. High-frequency currents for cutting and coagulation should be turned to the lowest possible setting of diathermy in order to avoid unnecessary burn injuries. At the end of operation, the cul-de-sac was punctured, with ultrasound guidance, to remove the intra-abdominal fluid. The urinary bladder was subsequently emptied. The irrigating fluid used in the operation was a solution of either 10% pentose or 10% dextrose in water. Serum electrolytes were checked routinely before and after the operation. About 3 months after operation, hysteroscopy was performed in each patient to confirm the regeneration of the mucosa over the resected area.

Results

Resection of submucous uterine myoma of six patients, and resection of uterine septum of two patients, were performed according to the three-contrasts method described above. Each resection was done within an hour. There were no traumatic complications. No patient required laparotomy during or after operation. Blood transfusions were not required in any case. Postoperative serum electrolytes revealed no significant change in any patient. All patients were discharged within 3 days.

Clinical follow-up on the six patients with submucous uterine myoma showed improvement of metrorrhagia and menorrhagia by measuring the number of pads or tampons used during menstruation and by examining the passage of blood clots (Table I). Postoperative hysteroscopic examinations revealed no intrauterine adhesion and that regeneration of endometrium at the operation site was normal. The results of resection of uterine septum on the other two patients are still being determined by follow-up studies.

Comment

Submucous uterine myoma, regardless of size, is one of the most annoying problems in clinical gynecology. It occasionally causes menorrhagia and metrorrhagia. Uterine septum is a cause of habitual abortion. Transcervical removal of nonmalignant intrauterine neoplasms and uterine septa has been reported elsewhere,[1-3] but operation performed by resectoscope or operating hysteroscope often carries a risk of accidental trauma, such as perforation of the uterine wall. To avoid such trauma during transcervical operations, concomitant laparoscopy has been used.[1-3] Even with concomitant laparoscopy, however, traumatic injury to the posterior uterine wall can be overlooked. Real-time ultrasound has also been used during gynecologic operations.[4] In nonpregnant patients with submucous uterine myomas, it is difficult to use ultrasound to ascertain the size of a fibroid when only the full bladder is used for contrast. It is also difficult to distinguish the posterior uterine wall from the surrounding structures. The three-contrasts method of ultrasonography may be used to overcome these problems.

Adding fluid in the cul-de-sac with a percutaneous intraperitoneal infusion provides a clear contrast to the posterior uterine wall and also mobilizes the intestine away from the uterus. Thus accidental injury to the uterus can be avoided. To obtain a clear picture when ultrasonography is used, the amount of fluid in the urinary bladder and the pressure of the transducer on the abdominal wall should be adjusted. Too much bladder volume or excessive pressure of the transducer

against the abdominal wall will reduce the amount of fluid in the cul-de-sac and diminish the discernible contrast.

Cooperation between the operating surgeon and the ultrasound operator is essential. The ultrasound operator should constantly inform the operating surgeon of the position of the resectoscope in order to avoid any accidental injury to the uterine wall. Both preoperative and postoperative ultrasonograms or hysterosalpingograms should be obtained to assure complete resection of myomas.

The advantage of using the pediatric resectoscope is that accurate observations of the intrauterine condition can be made without a need for cervical dilation. This procedure is difficult to perform with an adult-type resectoscope. Dilation of the cervical canal may cause uterine bleeding and blood clotting; it can also cause subsequent uterine contraction, which will interrupt operation. The three-contrasts method of ultrasonography makes it possible to monitor the posterior uterine wall, the submucous myoma, and the scope and thus enhances the safety of transcervical operations.

Prenatal ultrasonic diagnosis of multiple bowel atresias

M. Amanda Skoll, M.D., Gerald P. Marquette, M.D., and Emily F. Hamilton, M.D.
Montreal, Quebec, Canada

This case illustrates the course of an obstructive process through spontaneous perforation resulting in decompression of dilated bowel loops. The resulting meconium peritonitis appeared as fetal ascites. Postnatal investigations and laparotomy confirmed the diagnosis of a rare form of multiple congenital atresias of the bowel. (Am J Obstet Gynecol 1987;156:472-3.)

Key words: Prenatal diagnosis, bowel atresia, ascites, ultrasound

In this report, we describe a case of multiple atresias involving segments of the fetal gastrointestinal tract from stomach to rectum, with spontaneous perforation and subsequent meconium peritonitis.

Case report

Mrs. P. S., a 19-year-old primigravid woman, underwent ultrasound examination at 21 weeks' gestation that revealed multiple large fluid-filled loops of dilated bowel occupying the upper anterior region of the fetal abdominal cavity (Fig. 1). The amniotic fluid volume was normal and no other structural abnormalities were found.

Follow-up scanning from 25 to 28 weeks' gestation

From the Department of Obstetrics and Gynecology, Royal Victoria Hospital and McGill University.
Received for publication March 5, 1986; revised June 12, 1986; accepted August 12, 1986.

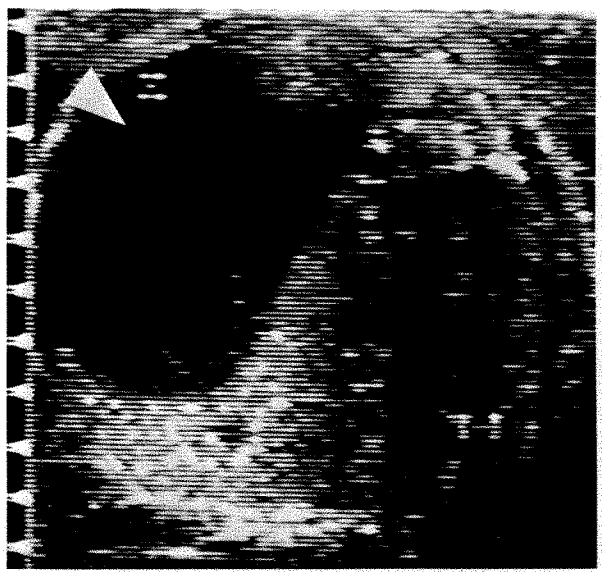

Fig. 1. Sonogram at 21 weeks' gestation. Dilated loop of bowel *(arrowhead)* in the upper part of the abdomen.

showed a reduction in the bowel distention and the appearance of fetal ascites (Fig. 2). However, from 28 to 33 weeks, an increase in dilatation became apparent and was accompanied by gradual disappearance of the ascites. Concurrent with resolution of the ascitic fluid, a calcified collection became evident in the right lower quadrant and remained constant.

At 35⅚ weeks' gestation, the patient was delivered spontaneously of a 2400 gm male infant. The baby had significant abdominal distention. Subsequent laparotomy revealed numerous sites of atresia throughout the bowel. Beginning in the stomach, multiple septa divided the intestine into segments of 2 to 3 cm, and the calcified deposits that had been previously noted on ultrasound were entirely within the lumen.

Comment

The presence of multiple distended loops of bowel is compatible with a distal obstructive process. Fetal ascites in combination with other signs of bowel obstruction suggests the occurrence of spontaneous perforation with subsequent meconium peritonitis.[1] Most commonly, meconium peritonitis results from obstruction secondary to meconium ileus or low atresia. Intraperitoneal calcifications have been described as a sequela of meconium peritonitis, due to the precipitation of tissue calcium by the fatty components of meconium.[1]

In our case, the initial picture was compatible with proximal intestinal obstruction. However, the subsequent appearance of ascites seemed to represent meconium peritonitis, more in keeping with low obstruction. Findings at laparotomy explained the ultrasound results by confirming both upper and lower bowel atresias. This rare condition[2] is associated with pasty calcification within the bowel lumen.

Fig. 2. Sonogram at 25 weeks' gestation. Decreased dilatation of bowel loops with presence of ascites *(arrowhead)*. Same level as Fig. 1.

This is the first known reported case of multiple atresias of this type described on ultrasonography. It demonstrates that intra-abdominal calcifications may not always represent intraperitoneal deposits. It also provides an example of the features of simultaneous upper and lower intestinal obstruction.

Effect of naloxone on fetal behavior near term

Domenico Arduini, M.D., Giuseppe Rizzo, M.D., Sergio Dell'Acqua, M.D., Salvatore Mancuso, M.D., and Carlo Romanini, M.D.

Rome and Ancona, Italy

Fetal behavior was studied after intravenous administration of either 0.4 mg of naloxone or an equal volume of saline solution in 54 healthy pregnant women near term. The number, duration, and amplitude of fetal heart rate accelerations increased after naloxone injection. The incidence of both gross fetal body movements and fetal breathing movements increased, especially in the first hour after naloxone administration. The distribution of fetal behavioral states was modified with a prevalence of active sleep and active awake states compared to the quiet sleep state. These data suggest that endorphins could be involved in the modulation of fetal behavior. (Am J Obstet Gynecol 1987;156:474-8.)

Key words: Naloxone, fetal heart rate, fetal behavior

Within the past few years several authors have shown the existence of ultradian and circadian rhythms of various fetal biophysical activities such as gross fetal body movements, fetal breathing movements, fetal eye movements, and fetal heart rate patterns.[1-3] The association of these activities and the increased understanding of fetal physiology have permitted the detection near term of behavioral states similar to those in the newborn infant.[4]

There is no account, however, of the mechanism regulating the alternation of these states. Recently it was suggested that the fluctuations of endorphin levels could be involved in the regulation of sleep states in adults.[5]

We investigated the effects of naloxone on echographic and cardiotocographic parameters to determine whether fetal endorphin levels are related to fetal behavior.

Material and methods

On the basis of several reports on the absence of detrimental effects of naloxone on healthy fetuses,[6, 7] the ethical committee of our institution approved this investigation. After informed consent had been obtained, the fetuses of 54 healthy pregnant women with gestational ages between 37 and 39 weeks were studied.

Studies were conducted in the afternoon, 2 hours after a standardized 1000 kcal lunch. Recordings were performed on patients lying in left semirecumbent position in a quiet room. They underwent simultaneous cardiotocographic and echographic examination.

Aloka SSD 248 and Aloka SSD 210 SX real-time scanners with 3.5 MHz multifocused linear transducers were used for examination of fetal head and trunk, respectively. Permanent records of all the images were made for later analysis on beta format videocassettes with use of Sony video recorders (Models SL HF 100 EC).

With use of a technique previously reported,[3] three parameters were evaluated: gross fetal body movements, fetal eye movements, and fetal breathing movements. These movements were simply classified as present or absent, without further differentiation as to the type of movement. Fetal heart rate was obtained by means of abdominal electrocardiography with a Hewlett-Packard 8030A cardiotocograph.

For the purpose of this investigation we identified fetal heart rate accelerations as increases of at least 15

*No differences were found between the variances as demonstrated by the F test. Significance was therefore evaluated by means of unpaired *t* test with variance assumed to be equal.

bpm for 15 seconds. Maximum amplitude and duration of acceleration were also measured.

According to Nijhuis et al.,[4] by means of a 3-minute moving window, four different patterns of fetal heart rate could be recognized: (A) heart rate stable with a variability of <10 bpm and isolated accelerations strictly related to movements; (B) heart rate with a variability >10 bpm and presence of numerous accelerations; (C) heart rate stable with a variability of >10 bpm and absence of accelerations; (D) heart rate unstable with large and long-lasting accelerations.

The association between fetal heart rate pattern, fetal body movement, and fetal eye movement makes it possible to detect four different behavioral states (quiet sleep, active sleep, quiet awake, and active awake) as reported in Table I. The simultaneous agreement of these three parameters was considered necessary for classification into one of these four states. In the absence of this condition epochs were classified as periods of no coincidence.

Fetal breathing movements were analyzed independently in consecutive 1-minute periods. The proportion of each consecutive 1-minute period during which fetal breathing movements were present was analyzed to evaluate its respective incidence (% time spent breathing). Moreover, the number of fetal body movements during the recordings was analyzed.

When two consecutive 3-minute quiet sleep epochs immediately preceded by the state of active sleep were identified, a person other than the investigators intra-

$\chi^2 = 71.2$; $p < 0.001$.

Table VII. Time interval and distribution of the changes of state after intravenous injection

	Lag-time (min)	*Active sleep*		*Quiet awake*		*Active awake*	
		n	%	*n*	%	*n*	%
Group A	9.6 ± 2.3*	15	55.5	0	0	12	44.5
Group B	16.4 ± 7.2*	23	85.1	3	11.1	1	3.8

$\chi = 13.9$; $p < 0.001$.
*F test ($F = 9.8$; $p < 0.001$). Unpaired *t* test with variance assumed to be unequal ($t = 4.7$; $p < 0.001$).

venously administered either 0.4 mg of naloxone hydrochloride (Narcan, Crinos, Como Villaguardia, Italy) or an equal volume of saline solution (0.9% sodium chloride). Observers involved in this investigation were not informed of the solution injected. The choice to administer either naloxone or placebo was randomized. Thus two groups were arranged: group A received naloxone (n = 27) and group B received a placebo (n = 27). Recordings were then continued for a further 2 hours. The experimental design is reported in Fig. 1.

Differences in fetal behavior between the two groups of patients were analyzed. All data are expressed as mean values ± standard deviations. Statistical analysis was performed by means of the χ^2 test and unpaired *t* test. Equality of variance was always determined by means of the F test.

Results

The overall characteristics of the two groups of patients are given in Table II. No differences were found between the two groups. Normal fetal outcomes confirmed the good health of the fetuses studied.

The intervals between the beginning of recording and naloxone or placebo administration were similar in the two groups (group A, 46.9 ± 12.3 minutes; group B, 49.3 ± 14.2 minutes). No differences were found in the echographic and cardiotocographic parameters preceding the intravenous infusion as shown in Table III.

The characteristics of fetal heart rate accelerations are shown in Table IV.

An increase in the number of accelerations in group 1 was especially evident in the first hour after treatment. Similar trends were found for the amplitude and duration of accelerations.

Table V gives the number of fetal body movements and the percent of time spent breathing. Both fetal body movements and fetal breathing movements increased after naloxone administration, especially during the first hour. The number of fetal body movements (Fig. 2) and the percent of time spent breathing (Fig. 3) are plotted as grouped means and standard deviations for each 10-minute interval after intravenous injection.

The percent of time in which a good view of fetal

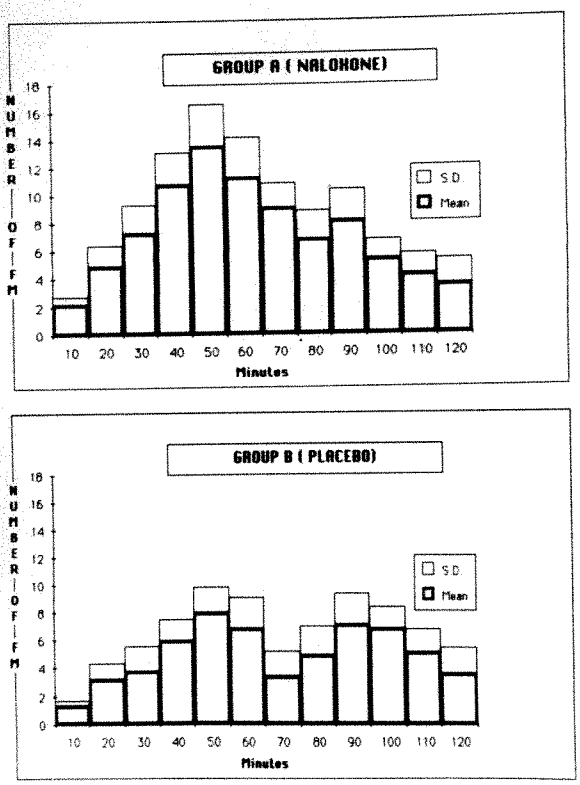

Fig. 2. The incidence of fetal body movements after endovenous injection of either naloxone (group A) or saline solution (group B).

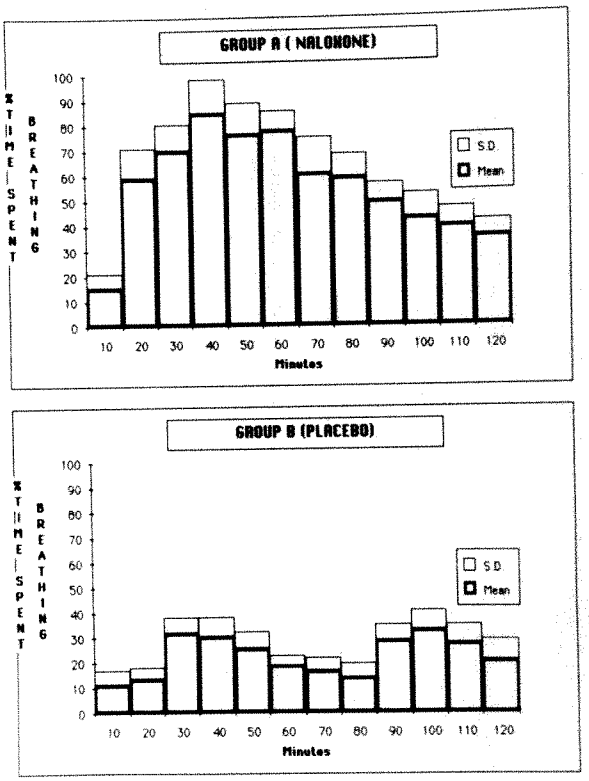

Fig. 3. Percent of time spent breathing after endovenous injection of either naloxone (group A) or saline solution (group B).

lens and trunk was obtained simultaneously with a reliable recording of fetal heart rate was similar in the two groups (group A, 91.9%; group B, 93.2%).

The distribution of fetal behavioral states is given in Table VI. We found an increase in the incidence of active sleep and active awake states and a decrease of the quiet sleep state in group 1 in comparison to the control group. No differences were found for the quiet awake state.

The lag-time between the intravenous injection and the change of state was measured. In group A, the quiet sleep state changed after 9.6 ± 2.3 minutes, while in group B (control) it changed after 16.4 ± 7.2 minutes. The F test demonstrated the difference between the variances of the lag-time ($p < 0.001$). An unpaired t test with variances assumed to be unequal was performed; the difference between the two groups is statistically significant ($p < 0.001$).

As shown in Table VII, in group A the quiet sleep state was followed in 15 cases (55.5%) by the active sleep state and in 12 (44.5%) by the active awake state. In group B the quiet sleep state was followed by the active sleep state in 23 cases (85.1%), quiet awake in three cases (11.1%), and active awake in one case (3.8%). This distribution is statistically significant (χ^2; $p < 0.001$).

Comment

There are few data on the effects of naloxone on fetal behavior. Goodlin[8] showed that flat fetal heart rate returned to a normal variability 20 minutes after intramuscular naloxone injection. Umans and Szeto[9] demonstrated in narcotic addict fetal lambs an increased number of fetal body movements, fetal eye movements, and fetal breathing movements after naloxone administration. Adamson et al.[10] found that the administration of naloxone increased the incidence of fetal breathing movements in the fetal lamb.

Until now, however, no data were available on the effects of naloxone on the behavior of the healthy human fetus. Our results show an increase in the number of fetal heart rate accelerations, fetal body movements, and fetal breathing movements, within 10 minutes of intravenous naloxone administration. Moreover, we found a modification in the distribution of fetal behavioral states with a prevalence of the active sleep and active awake states.

The mechanism regulating fetal behavior is still unknown. Nathanielsz et al.[11] found a relationship between the alternation of fetal behavior and uterine contractures in the pregnant sheep. The mechanisms involved may include small falls in the level of fetal oxygenation or compression of the fetal body. Hofmeyr

et al.,[12] however, recently demonstrated that the uterine contractions are rarely found in association with the rhythms of fetal behavior.

Terao et al.[13] found a biphasic pattern of heart rate in anencephalic fetuses with traces of cerebral cortex and normal or hypoplastic midbrain. Moreover, the aplasia of midbrain is characterized by the loss of biphasic pattern and the reduction in the number of accelerations. Thus the occurrence of accelerations and ultradian rhythms of fetal heart rate seems to be related to the presence of midbrain.

We have previously suggested that maternal plasma cortisol could be involved in the regulation of fetal behavior through the modulation of fetal pituitary gland.[14] Preliminary findings[15] support this hypothesis: the inhibition of the fetal pituitary-adrenal axis, after triamcinolone administration, causes modifications of fetal behavior similar to those found in this investigation.

The mechanism of action could be the same. The pituitary gland secretes adrenocorticotropic hormone and β-endorphin concomitantly, since both are derived from a common precursor, namely, pro-opiomelanocortin.[16] Therefore triamcinolone suppresses the secretion of both adrenocorticotropic hormone and β-endorphin, whereas naloxone antagonizes the action of β-endorphin.

Further studies are required for a complete understanding of the mechanisms regulating fetal behavior, but these data suggest that endorphins could be involved in the modulation of fetal behavior.

Immunocytochemistry of human chorionic gonadotropin in human chorionic villi

Kunshige Hamasaki, M.D., Yasushi Okamura, M.D., Hiroshi Ueda, Ph.D., Hirohiko Kagawa, Ph.D., and Sunao Fujimoto, M.D.

Kitakyushu, Japan

The immunocytochemical localization of human chorionic gonadotropin was investigated in chorionic villi from the seventh to twelfth week of gestation. By the light microscopic peroxidase-antiperoxidase tecnhique, positive reactions of human chorionic gonadotropin were found exclusively in the syncytiotrophoblast. Immunoelectron microscopy by means of the protein A–gold technique reveals localization of the immunoreactive gold particles in two kinds of membrane-bound granular inclusions in this cell; one type is granules of 200 to 300 nm in diameter with moderate electron density and the other is large electron-dense bodies of 500 to 1000 nm. The former seems to be Golgi-derived secretory granules that play a role in the release of human chorionic gonadotropin from the syncytiotrophoblast. Although the origin of the latter is still uncertain, a certain amount of this hormone might be stored or treated by lysosomal digestion in the large bodies during these stages. (Am J Obstet Gynecol 1987;156:479-83.)

Key words: Human chorionic villi, syncytiotrophoblast, human chorionic gonadotropin, immunoelectron microscopy

The localization of human chorionic gonadotropin in human placentas has been studied by several investigators. An earlier worker[1] considered cytotrophoblast (Langhans' cell) as a human chorionic gonadotropin–producing cell on the basis of the correlation between the hormonal assay and the cell number.[1] With the light microscopic immunofluorescence and immunoperoxidase techniques together with the specific antisera against human chorionic gonadotropin, localization of this hormone has been demonstrated in the syncytiotrophoblast[2] and in both the trophoblastic layers.[3] Furthermore, recent light microscopic immunofluorescence studies reported that the β-subunit of human chorionic gonadotropin was located in the syncytiotrophoblast but human chorionic gonadotropin and its α-subunit were in both the layers.[4, 5]

For the demonstration of human chorionic gonadotropin at electron microscopic levels, the peroxidase-labeled antibody technique has been used previously.[6-9] However, these reports have been controversial as to the precise localization of this hormone in the trophoblastic cells. We demonstrate in this paper the ultrastructural localization of human chorionic gonadotropin in human placental chorionic villi by the application of the protein A–gold technique.[10]

Material and methods

Human placentas of 7, 9, and 12 weeks of gestation obtained from natural and elective abortions were used for the present study. For light microscopic observations, specimens were fixed in Bouin's solution for 24 hours at room temperature and routinely embedded in paraffin. Specimens for electron microscopy were fixed in Zamboni solution[11] for 18 hours at 4° C. After washing in 0.1 mol/L phosphate buffer containing 10% sucrose, most of them were postfixed with 1% osmium tetroxide in 0.1 mol/L phosphate buffer for 1 hour at 4° C. All specimens were dehydrated in graded concentrations of acetone and embedded in epoxy resin.

The unlabeled antibody peroxidase-antiperoxidase technique was used for the light microscopic immunocytochemistry. The working dilution of the antiserum against human chorionic gonadotropin (Dako Immunoglobulins) ranged from 1:500 to 1:2000. For the immunoelectron microscopy, the protein A–gold technique was used with some slight modifications.[12, 13] The etching treatment with saturated sodium metaperiodate was done for 1 hour only in osmium-postfixed specimens to restore the hormonal antigenicity. Ultrathin sections mounted on uncoated 150-mesh nickel grids were placed on 1% egg albumin in phosphate-buffered saline for 15 minutes and then incubated with specific rabbit antisera against human chorionic gonadotropin (Dako Immunoglobulins; UCB Bioproducts) for 2 hours. These two antisera did not show any

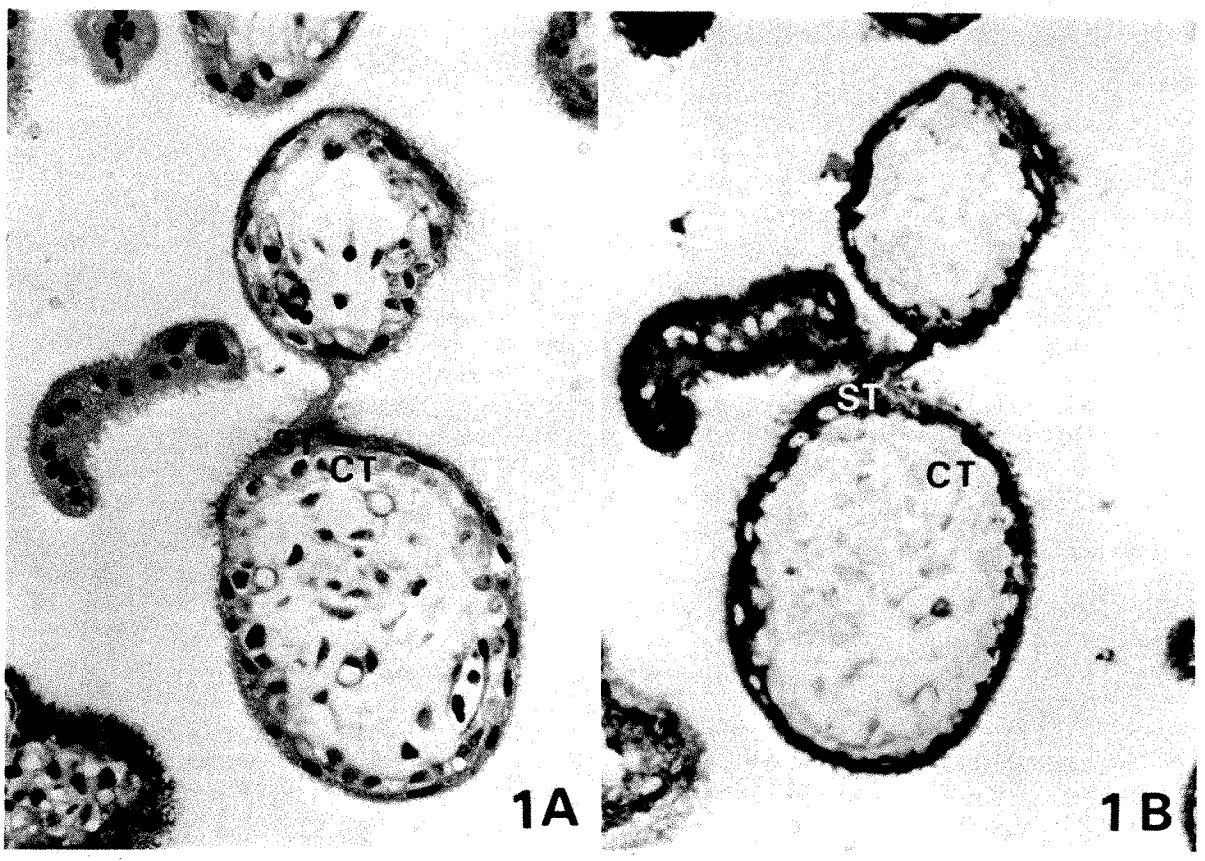

Fig. 1. Serial 4 μm sections of the chorionic villi at 7 weeks of gestation stained with Masson's trichrome *(A)* and with the peroxidase-antiperoxidase technique and anti–human chorionic gonadotropin serum *(B)*. Immunoreaction of human chorionic gonadotropin is localized only in the syncytiotrophoblast *(ST)*. *CT*, Cytotrophoblast. (×1300.)

difference in labeling intensity and specificity. The working dilution of the antisera ranged from 1:500 to 1:2000. After washing in phosphate-buffered saline for 15 minutes, the grids were placed on the protein A–gold solution diluted 1:10 in phosphate-buffered saline for 1 hour, stained with both uranyl acetate and lead nitrate, and examined with a JEM 100 CX electron microscope. The specificity of the immunolabeling was confirmed by the following controls: (1) replacement of the anti–human chorionic gonadotropin for normal rabbit serum or antisera against human prolactin, human growth hormone, and human adrenocorticotropic hormone (Dako Immunoglobulins) and (2) absorption of the anti–human chorionic gonadotropin with human chorionic gonadotropin (UCB Bioproducts).

Results

Fig. 1, *A*, shows human placental chorionic villi at 7 weeks of gestation stained with Masson's trichrome. In the adjacent 4 μm section incubated with anti–human chorionic gonadotropin at a concentration of 1:1000 and stained with the peroxidase-antiperoxidase technique, positive reactions of human chorionic gonadotropin were found exclusively in the syncytiotrophoblast (Fig. 1, *B*). Few nonspecific reactions were observed if normal rabbit serum or the other antisera (anti–human prolactin and anti–human growth hormone) were replaced for the specific antiserum.

In electron microscopy of the Zamboni-osmium–fixed sections at 7 weeks of gestation, the syncytiotrophoblast develops the Golgi apparatus and contains abundant membrane-bound inclusions of varying size and electron density, granules of 200 to 300 nm in diameter with moderate electron density *(MG)*, large bodies of 500 to 1000 nm *(LB)*, and large vacuoles of 500 to 1000 nm with various contents *(LV)* as shown in Fig. 2, *A* and *B*. Our electron micrographs show that the granules *(MG)* are derived from the Golgi apparatus *(GA*, Fig. 2, *A*) and aggregate to the apical cell surface (Fig. 2, *B*).

In the specimens labeled with the protein A–gold technique, the gold particles of 10 to 20 nm in diameter are preferentially concentrated on the Golgi-derived granules and large bodies (Fig. 3, *A* and *B*). The spec-

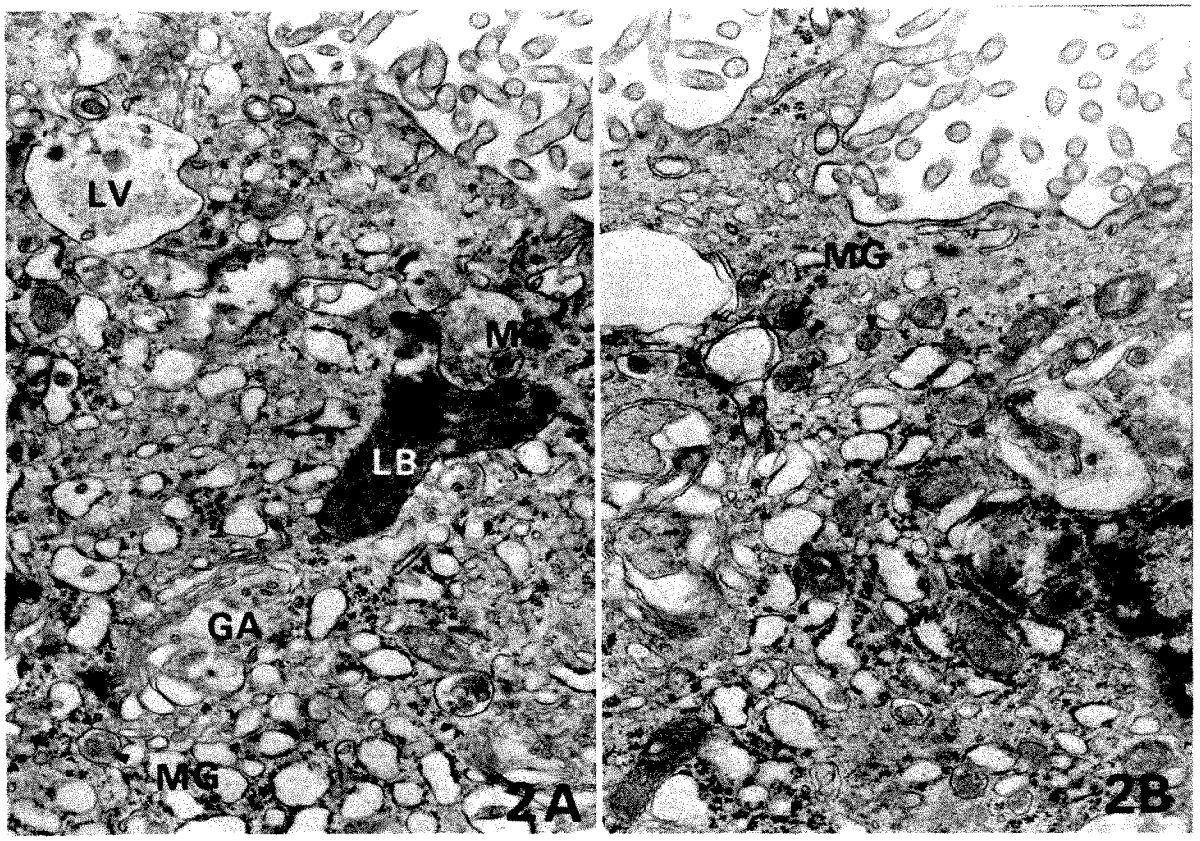

Fig. 2. Electron micrograph of the syncytiotrophoblast at 7 weeks of gestation showing three kinds of membrane-bound inclusions: granules of 200 to 300 nm with moderate electron density *(MG)*, large electron-dense bodies *(LB)*, and vacuoles *(LV)*. The granules *(arrowheads)* often exist near the Golgi apparatus *(GA)*, as shown in *A*, and are concentrated in the apical cell region, as shown in *B*. (Zamboni-osmium. *A*, ×23,000. *B*, ×25,000.)

imens fixed only in Zamboni solution remain more antigenic sites resulting in heavier labeling than those postfixed in osmium but yield much less satisfactory results, especially in the preservation of these inclusions (Fig. 4). Few nonspecific reactions were observed in the large vacuoles.

In the specimens at 9 and 12 weeks of gestation, these immunoreactive granular inclusions decrease considerably in number. Very few gold particles were observed on the cytoplasmic matrix and chorionic space in the controls when the specific anti–human chorionic gonadotropin serum was substituted for normal rabbit serum (Fig. 5, *A*) and the antiserum was absorbed with human chorionic gonadotropin (Fig. 5, *B*).

Comment

To date, four articles have described ultrastructural localizations of human chorionic gonadotropin in human placentas with the use of the peroxidase-antiperoxidase technique.[6-9] Although they reported localization of the reaction products either on the membranes of rough endoplasmic reticulum or in the cavities of apical vacuoles, the fine structure of these cytoplasmic organelles and inclusions was poorly preserved under methacrylate-embedded cryosections.

The present protein A–gold technique demonstrates that the antigenicity of human chorionic gonadotropin is preferentially located in Golgi-derived granules of 200 to 300 nm in the syncytiotrophoblast. From our electron micrographs, these granules seem to be segregated from the Golgi apparatus and released by exocytosis as secretory granules from the apical cell surface into the maternal circulation. Thus the present findings argue for the previous light microscopic immunocytochemical reports indicating human chorionic gonadotropin localization only in the syncytiotrophoblast.[2]

A few immunofluorescence studies reported that the β-subunit of human chorionic gonadotropin was also located in the cytotrophoblast.[4, 5] Therefore, we examined immunocytochemical localizations of α- and β-subunits of human chorionic gonadotropin by means of light microscopic peroxidase-antiperoxidase and immunoelectron microscopic protein A–gold techniques with the use of the specific antisera against both α- and

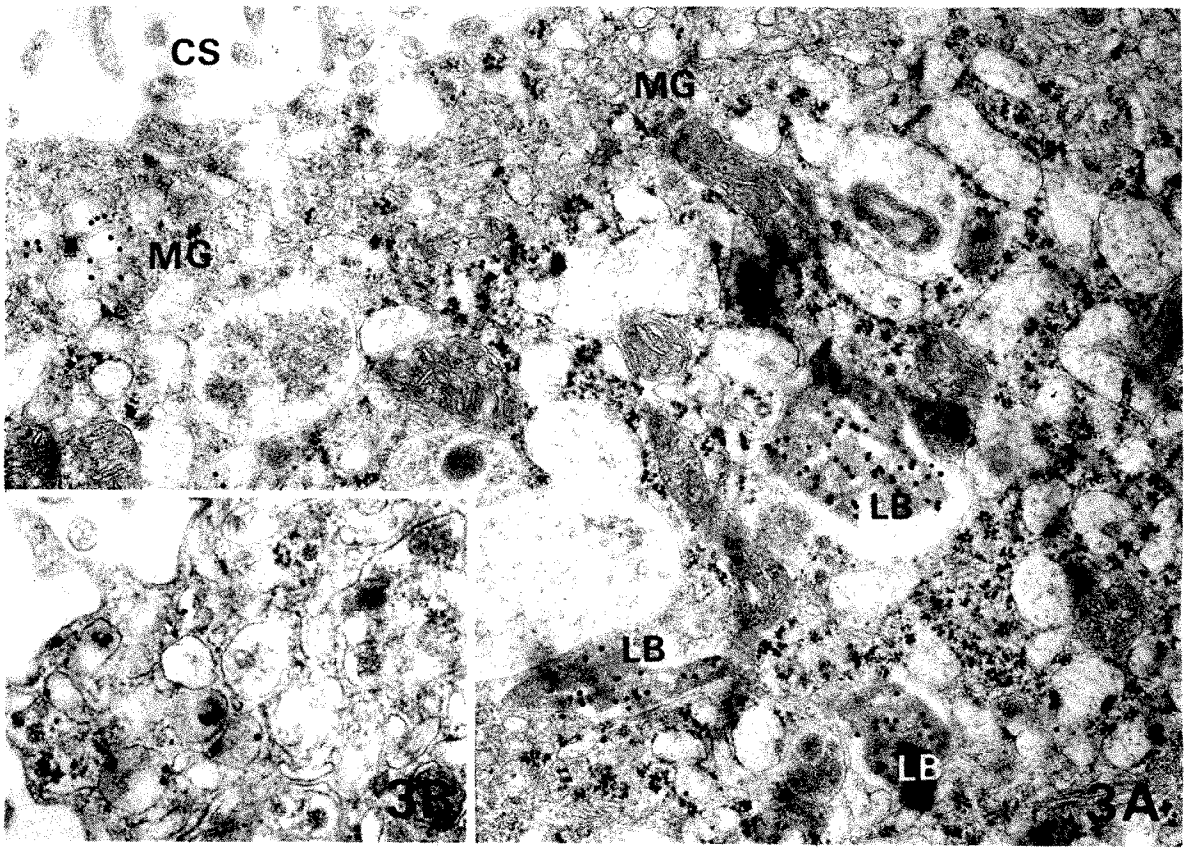

Fig. 3. Immunoelectron microscopic localization of human chorionic gonadotropin in the syncytiotrophoblast at 7 weeks of gestation. The gold particles are preferentially located on granules *(MG)* aggregating near the chorionic space *(CS)* and large bodies *(LB)*, as shown in *A*. The granules, although considerably reduced in electron density in this immunostaining section, are clearly distinguishable from the neighboring enlarged cisterns *(B)*. (Zamboni-osmium. *A*, ×29,000. *B*, ×40,000.)

β-subunits of human chorionic gonadotropin (UCB Bioproducts).[14] In both techniques, we did not obtain any specific labeling against these two antisera in the cytotrophoblast. Thus we conclude that the cytotrophoblast does not contain any immunospecificity against human chorionic gonadotropin and its subunits.

The present study reveals that the large body is another antigenic site of human chorionic gonadotropin in the syncytiotrophoblast. These do not seem to be secretory granules judging from their ultrastructure. Similarly, in the pituitary gland, it is well known that cells producing luteinizing hormone and follicle-stimulating hormone sometimes contain two kinds of granules, small secretory granules and large granules. The concentration of human chorionic gonadotropin in blood serum is high in the first trimester and rapidly declines thereafter.[15] Also, in the present observation, the granules have considerably decreased in number at 12 weeks. On these grounds, we speculate at present that the large bodies might play a role in reservoirs of the hormones during early gestation or in crinophagic lysosomal structures that digest the hormone as already mentioned in the prolactin cells.[16] At any rate, more detailed morphologic studies are necessary to elucidate the precise function of this inclusion in the syncytiotrophoblast, and such studies are now in progress in our laboratory.

Nonsurgical therapy to preserve oviduct function in patients with tubal pregnancies

Kihyoe Ichinoe, M.D., Norio Wake, M.D., Naoko Shinkai, M.D., Yoshihiro Shiina, M.D., Yukio Miyazaki, M.D., and Toshinobu Tanaka, M.D.

Sapporo, Japan

Surgical treatment for tubal pregnancies greatly impairs the subsequent fertility of patients because of salpingectomy and its complicated adhesions. Nonsurgical methotrexate therapy was developed to avoid such complications. Although early detection was of prime importance, resolution of ectopic pregnancy was obtained in 22 patients (95.7%) with methotrexate administration alone. Patency of the oviducts was evaluated with hysterosalpingography and/or laparoscopy in 19 patients after termination of methotrexate treatment. In 10 of 19 patients (52.6%), complete patency of the involved oviduct confirmed the validity of this regimen. Severe side effects were not observed in any of the 23 patients. (Am J Obstet Gynecol 1987;156:484-7.)

Key words: Tubal pregnancy, methotrexate, salpingectomy

The term ectopic pregnancy is applied to a pregnancy that follows implantation of the fertilized egg on any tissue other than the mucous membrane lining of the uterine cavity. The most common type of ectopic pregnancy is that which occurs in the tube. Surgical treatment has been used once the tubal pregnancy is diagnosed. However, irrespective of the operative procedures, utilized, subsequent fertility has been impaired because of damage to the uninvolved tube. This damage has been assumed to be a sequel of the irritating factors of a blood clot in the peritoneal cavity and of operative procedures that cause fibrosis and obstructive adhesions of the oviduct. Thus excision of ectopic pregnancies or salpingostomy with reparative procedures has been used in an attempt to improve fertility. However, repeated tubal pregnancy in patients who underwent plastic surgery of the tube is not unusual.

The current availability of sophisticated clinical modes of diagnosis of pregnancy has also provided the possibility of early detection of ectopic pregnancy. Examinations by the use of B-scope scanning are of prime importance. The former is routinely applied for estimation of the date of conception and localization of the implantation site in all patients with early stage pregnancy. This system has made possible the early diagnosis of ectopic pregnancy before any signs of termination appear. Urinary and serum human chorionic gonadotropin measurements and endometrial curettage are also useful to establish the diagnosis in such cases.

Methotrexate is a folic acid antagonist that has been widely used for cancer treatment. Impairment of nucleic acid synthesis is responsible for the inhibition of tumor cell division. A similar effect was obtained with trophoblasts of abdominal pregnancies[1] since trophoblasts possess high proliferative activity. This idea has led to nonsurgical methotrexate treatment in patients with tubal pregnancy in order to conserve tubal function. In this study the efficacy of this treatment is discussed and the data obtained from 23 patients are analyzed.

Material and methods

Tubal pregnancy was diagnosed in 23 patients by means of B-scope scanning, urinary human chorionic gonadotropin measurements, endometrial currettage, and clinical course. The diagnosis was established in all cases before indications of termination of pregnancy. Methotrexate (0.4 mg/kg/day for 5 days) was administered intramuscularly to these patients. These courses were generally given every other week, although the schedule was occasionally altered by the degree of severity of side effects in the patients. The total dosage of methotrexate was determined with reference to the total urinary human chorionic gonadotropin titer in the patients measured by radioimmunoassay (Mochida Pharma. Co.). Resolution of tubal pregnancy was diagnosed in patients with urinary human chorionic gonadotropin levels that decreased to 20 IU/L. Patients were followed up for 2 to 3 months after the termination of methotrexate therapy. The patency of

the oviduct was evaluated by hysterosalpingography and/or laparoscopy.

Results

The ages of the 23 patients ranged from 20 to 41. Urinary human chorionic gonadotropin values in these patients were generally lower (80 to 16,000 IU/L) than those in intrauterine pregnancies (Table I). The left oviduct was involved in 11 cases and the right in 10 cases. The exact localization of the implantation site could not be confirmed in the remaining two cases. Methotrexate therapy was chosen for eight patients with a previous salpingectomy and in another 15 patients without such operation. Resolution was obtained in 22 patients with methotrexate administration alone. The remaining patient underwent immediate operation because of tubal rupture during the treatment. The total doses of methotrexate used in these 22 patients ranged from 60 to 300 mg (mean 151.1 mg). These doses tended to correspond to the urinary human chorionic gonadotropin titer before treatment; 60 to 150 mg (mean 93 mg) of methotrexate was sufficient to produce resolution in cases with urinary human chorionic gonadotropin levels <1000 IU/L, although 75 to 300 mg (mean 191 mg) was necessary in cases where the urinary human chorionic gonadotropin level was >2000 IU/L. The length of time required for the urinary human chorionic gonadotropin levels of patients to reach 20 IU/L with methotrexate treatment ranged from 6 to 47 days (mean 29.7 days). The mean in five patients with human chorionic gonadotropin titers <1000 IU/L before treatment was 18.6 days (6 to 30 days), although 35.9 days was necessary in 17 patients with levels >2000 IU/L.

The patency of bilateral oviducts was evaluated in 19 patients with hysterosalpingography and/or laparoscopy after termination of the methotrexate therapy (Table II). Those patients were then subdivided into two groups for exact evaluation, seven patients with a history of previous salpingectomy on either oviduct and 12 patients without such a history. Two patients (28.6%) had complete patency of the involved oviduct, although passage of the contrast medium was partially interrupted in three and completely interrupted in two patients in the former group. The patency of the uninvolved oviduct in the group without a history of salpingectomy could be demonstrated in all patients except in one case (Case 22) with peritubal adhesions. Normal passage of the contrast medium through the involved tube was observed in eight patients (58.3%), although obstruction and peritubal adhesions, respectively, were shown in two patients in this group. A high rate of impairment of passage through the involved oviduct was shown in the group with previous salpingectomy.

A further comparison of the rate of patency of the involved oviduct was performed between the group with early gestation (<7 weeks of pregnancy) and the group at a relatively advanced stage (>8 weeks of pregnancy). A higher success rate was obtained in the for-

*Cases in which salpingectomy was done for the previous tubal pregnancy.

mer (five of eight, 62.5%) than in the latter (five of 11, 45.5%), although the number of case evaluated was still small. The group without previous salpingectomy and with gestation of <7 weeks obtained the highest rate of patency of the involved oviduct (five of six, 83.3%). As a result, in 10 of 19 patients (52.6%) complete patency of the involved oviduct function was obtained with methotrexate administration alone.

Four patients had other pregnancies subsequent to the termination of methotrexate therapy in spite of the relatively short period of observation. Two patients (Cases 3 and 22) were delivered of three normal neonates although one (case 17) had a spontaneous abortion. The remaining patient (Case 4), who underwent elective abortion because of an economic problem, was especially noteworthy. Because the left tube of this patient had already been removed, a methotrexate regimen for treatment of a right tubal pregnancy was undertaken in the present study. This resulted in resolution of the tubal pregnancy, but there was impairment of passage of the contrast medium. However, she still retained reproductive capability.

Severe side effects were not observed in any of the 23 patients with administration of a total of 60 to 300 mg of methotrexate. Slight elevations of serum glutamic oxaloacetic transaminase and serum glutamic pyruvic transaminase, and slight bone marrow suppression were noted in four cases and one case, respectively.

Comment

Methotrexate treatment for extrauterine pregnancies was initially used in cases of abdominal pregnancy.[1-3] The prompt deterioration of the placenta produced by methotrexate administration may bring about resolution without sequelae, although surgical manipulation of the placenta has generally resulted in profuse hemorrhage. Similar trials undertaken for cervical and interstitial pregnancies also indicated the effectiveness of this therapy.[4] The rationale for the use of methotrexate in these instances was to bring about a prompt destruction of placental trophoblastic activity, with the assumption that this would be associated with a concomitant decrease in placental vascularity and thereby a marked restriction of the potential of hemorrhagic complications of the retained placenta. Methotrexate therapy for tubal pregnancies has also been based on the expectation of similar effects.

Surgical treatments greatly impair subsequent fertility in patients because of salpingectomy and its complicated adhesions. Simultaneous tuboplasty also frequently results in repeated tubal pregnancy. Nonsurgical methotrexate treatment was considered to avoid such complications. Although early detection is of prime importance in this respect, recent advances in B-scope scanning can produce the diagnosis in the stage before the pregnancy terminates. In fact, B-scope scanning resulted in early detection in 23 patients of the present study, and resolution occurred with methotrexate administration alone in all cases except one. However, preservation of the oviduct function should be also considered. In the present study, in 52.6% of the involved oviducts (10 tubes), complete patency occurred together with resolution of tubal pregnancy, thus confirming the clinical validity of this regimen.

The remaining nine tubes (47.4%) showed various degrees of interruption of passage on hysterosalpingography. The causal mechanisms responsible for this complication must be considered. In five patients with previous salpingectomy it is likely that the presence of peritubal adhesions, probably as the result of salpingectomy, caused the current tubal pregnancy as well as the passage interruption after the termination of methotrexate therapy. However, the details responsible for the complication remain to be clarified in the other four cases in which salpingectomy had not been performed. The erosive action of trophoblasts and the separation of the ovum from the tubal wall are sometimes re-

sponsible for bleeding into oviducts and from the fimbriated orifice, which may be filled with clots. Although the causal factors resulting in subsequent tubal pregnancy should be accounted for, it is likely that such bleeding into the oviduct gives rise to either peritubal adhesion or obstruction. This would suggest that methotrexate administration should be begun at the stage before the appearance of bleeding into the oviduct. The highest success rate obtained in the group without previous salpingectomy and in which the gestation was <7 weeks may support this idea. However, further accumulation of data is necessary to confirm the validity of this regimen.

The total dosage of methotrexate used in the present study was evidently less than the one used for patients with trophoblastic diseases. Only slight suppressions of liver and bone marrow functions have been observed. Those indicate the safety of methotrexate treatment for patients with tubal pregnancies, although imminent influences on offspring of women receiving methotrexate remain unknown. Literature on the topic[5-8] indicates that 3% to 10% of neonates born to mothers who had received chemotherapeutic regimens had congenital anomalies. These indications are at variance with our data (Shinkai N, Wake N, Ichinoe K, Shiina Y. unpublished data) that none of 53 patients had such anomalies. The cause of this difference is uncertain, but it is unlikely that a relationship exists between the incidence of congenital anomalies and the administration of chemotherapeutic agents because the latter has not been carried out in patients during pregnancy. Rather the degree of germ cell damage created by the agents is important to evaluate the safety of this regimen. This would be reflected by the rates of spontaneous abortion or some kinds of abnormal pregnancies. We are aware of 449 pregnancies after the termination of chemotherapy in the literature.[5-10] Sixty-five spontaneous abortions occurred, for a rate of 14.5%, which is not different from that in data of the control population without any kind of chemotherapy.[6-8] Thus previous data indicate that the rate of fetal wastage presumably resulting from the injured germ cells was not high, suggesting safety for offspring of women receiving methotrexate therapy. However, this should be investigated further since the available data are insufficient at this time.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Position Statement on Gestational Diabetes Mellitus

Formulated by the American Diabetes Association, Inc.

I. Definition, Detection, and Diagnosis
   A. Definition
      Gestational diabetes mellitus is defined as carbohydrate intolerance of variable severity with onset or first recognition during the present pregnancy. The definition applies regardless of whether insulin is used for treatment or the condition persists after pregnancy but does not exclude the possibility that the glucose intolerance may have antedated the pregnancy
   B. Detection
      All pregnant women should be screened for glucose intolerance because selective screening based on clinical attributes or past obstetric history has been shown to be inadequate. Pregnant women who have not been identified as having glucose intolerance before the twenty-fourth week should have a screening glucose load between the twenty-fourth and the twenty-eighth week consisting of 50 gm of oral glucose given without regard to time of the last meal or the time of day. The venous plasma glucose level is measured 1 hour later. A value of ≥140 mg/dl is recommended as a threshold to indicate the need for a full diagnostic glucose tolerance test
   C. Diagnosis
      Diagnosis is based on results of the 100 gm oral glucose tolerance test during pregnancy interpreted according to the diagnostic criteria of O'Sullivan and Mahan.[1] Definitive diagnosis requires that two or more of these venous plasma glucose concentrations be met or exceeded: fasting, 105 mg/dl; 1 hour, 190 mg/dl; 2 hours, 165 mg/dl; 3 hours, 145 mg/dl

II. Obstetric and Perinatal Considerations
   A. The offspring of mothers who experience fasting (≥105 mg/dl) and postprandial (≥120 mg/dl) glycemia are at greater risk for intrauterine or neonatal death, and such mothers must undergo careful antepartum fetal surveillance. Perinatal mortality in offspring of patients with gestational diabetes who maintain normal fasting and postprandial glucose levels may not be increased above that observed in the general population under conditions of *optimum* obstetric care and restitution of fasting and postprandial plasma glucose levels to normal limits. All patients with gestational diabetes are at significant risk for fetal macrosomia as well as other neonatal morbidity, including hypoglycemia, hypocalcemia, polycythemia, and hyperbilirubinemia

III. Therapeutic Strategies
   A. Close surveillance of mother and fetus must be maintained in all instances of gestational diabetes mellitus. Maternal surveillance should be directed toward monitoring for elevations of fasting or postprandial glucose levels in capillary blood or venous plasma and designed to detect any deterioration of glucose homeostasis as gestation proceeds
   B. Monitoring of maternal urinary glucose is no longer deemed adequate or sufficient
   C. Increased fetal surveillance is appropriate, but the starting time, frequency, and techniques used should depend on the cumulative degree of risk that the fetus is believed to bear
   D. All women with gestational diabetes mellitus should receive nutritional counseling consistent with the recommendations for caloric distribution proposed by the American Diabetes Association. Intake of sucrose should be limited
   E. If dietary management does not consistently maintain the fasting plasma glucose level ≤105 mg/dl and/or the 2-hour postprandial plasma glucose level ≤120 mg/dl on two or more occasions within a 2-week interval, insulin therapy is initiated in many centers. Self-monitoring of blood glucose is a requirement for effective insulin therapy. If insulin is prescribed, only highly purified nonbeef insulin preparations should be used
   F. Oral hypoglycemic agents cannot be recommended during pregnancy
   G. Breast-feeding should be encouraged in women with gestational diabetes mellitus

This statement is based on the summary and recommendations of the Second International Workshop-Conference on Gestational Diabetes Mellitus (published in Diabetes 1985;34:123-6). Approved by the Board of Directors of the American Diabetes Association, Inc., March 8, 1986, and reproduced with permission from the American Diabetes Association, Inc.

IV. Prognostic considerations
    A. Women in whom gestational diabetes mellitus is diagnosed should be evaluated post partum to detect diabetes early in its course. They should be evaluated initially at the first postpartum visit by a 2-hour oral glucose tolerance test with a 75 gm glucose load

Human Papillomaviral Infection and Lower Genital Tract Neoplasia: An Advanced Course for Pathologists and Clinicians, May 7, 8, 9, 1987, Doubletree at Concourse Hotel, Atlanta, Georgia. Directed by Dr. Richard Reid and sponsored by The Regional Cancer Center–Saint Joseph's Hospital of Atlanta. For further information contact: Mary Claire Jones, Director of Educational Services. Tel.: (404) 851-7025.

High-Risk Obstetrics, April 2-4, 1987, Chicago, Illinois. Sponsored by the Cook County Graduate School of Medicine. For additional information contact the Registrar's Office. Toll-free number: Illinois 1 (800) 621-4649, outside Illinois 1 (800) 621-4651.

Current Concepts in Obstetrics and Gynecology Focusing on Endometriosis, March 27-28, 1987, Inn on the Park, Four Riverway, Houston, Texas. Presented by Baylor College of Medicine, Department of Obstetrics and Gynecology. For information contact: Lila K. Lerner, Program Coordinator, The Office of Continuing Education, Baylor College of Medicine, One Baylor Plaza, Houston, TX 77030. Tel.: (713) 799-6020.

The Annual International Reproductive Health Seminar, November 4-7, 1987, The Sheraton British Colonial, One Bay Street, Nassau, Bahamas. Sponsored by IPARC International Population and Reproduction Council. For further information contact: Howard A. Engle, M.D., Director General, IPARC, 975 Arthur Godfrey Road, Suite 102, Miami Beach, FL 33140. Tel.: (305) 531-0047.

Fourth Annual Houston Everett Memorial Course in OB-GYN Urology, Saturday, April 25, 1987, The Johns Hopkins Medical Institutions, Baltimore, Maryland. 9 AMA Category I credits; application has been made for other appropriate credits. Sponsored by the Department of Gynecology and Obstetrics, The Johns Hopkins Medical Institutions. For information contact: Program Coordinator, Office of Continuing Education, The Johns Hopkins Medical Institutions, Turner 22, 720 Rutland Ave., Baltimore, MD 21205. Tel.: (301) 955-6046.

The Pacific Coast Obstetrical and Gynecological Society Ted Adams Scholarship Committee invites applications for an award of $7,500 to be given in 1987 to a student, resident, or practicing physician residing in the geographical area of the Society (Alaska, Arizona, British Columbia, California, Hawaii, Idaho, Nevada, Oregon, Utah, and Washington). Applicants should submit a descriptive outline detailing their educational background, their present status, and how the award would be used in pursuit of knowledge that could elucidate and contribute to understanding of some aspect of normal or abnormal structural, functional, or behavioral component of human reproductive biology. All applications received by July 1, 1987, will be considered by the committee. The decision of the committee will be final and will be announced at the annual meeting of the Society, September 27 to October 2, 1987, at the Lodge at Pebble Beach, Pebble Beach, California. Address applications to: PCOGS Scholarship Committee, 707 Cobb Medical Center, Seattle, WA 98101.

Ninth Practical Course in Colposcopy and Cervicovaginal Histopathology in English. Demonstration of the use of Dr. Cartier's Diathermy Loop. Paris, France, September 21-25, 1987. For further information contact: Dr. R. Cartier, 20, rue des Cordelieres, F 75013 Paris, France. Tel.: (1) 43 36 04 46.

Reproductive Endocrinology and General Gynecology, May 31–June 6, 1987, Palmetto Dunes Resort, Hilton Head Island, South Carolina. Sponsored by the Department of Gynecology and Obstetrics, The Johns Hopkins Medical Institutions. Credits: 34 AMA. This program has been approved for 33 Cognates, Formal Learning, by the American College of Obstetricians and Gynecologists. For information contact: Jeanne Ryan, Program Coordinator, Office of Continuing Education, The Johns Hopkins Medical Institutions, 720 Rutland Ave., Turner 22, Baltimore, MD 21205. Tel.: (301) 955-6046.

The Role of β-Lactamase Inhibitor Combinations in the Management of Obstetric-Gynecologic Infections

Richard L. Sweet, M.D., *Chairman*
San Francisco, California

The following papers are selected from presentations given at the symposium, "The Role of β-Lactamase Inhibitor Combinations in the Management of Obstetric-Gynecologic Infections," held at the Beverly Wilshire Hotel, Beverly Hills, California, March 7-9, 1986.

This symposium was supported by a grant from Roerig, a division of Pfizer Pharmaceuticals.

Microbiology of the female genital tract

Ronald S. Gibbs, M.D.
San Antonio, Texas

Patients who contract genital tract infections are predominantly young, are otherwise healthy, and generally respond well to treatment for bacterial infections. These infections are most commonly polymicrobial in etiology, with several noteworthy exceptions. Often there is an inciting event such as childbirth, surgical intervention, pregnancy termination or intrauterine contraceptive device insertion. With treatment, prognosis for cure is excellent; however, sequelae such as recurrent infections, infertility, or ectopic pregnancy can be serious. Bacteria encountered in the female genital tract can be divided into aerobic and anaerobic organisms. Among the aerobic gram-positive organisms, several varieties of streptococci such as Group B streptococci and enterococci occur frequently. *Staphylococcus aureus* is an infrequent but important pathogen. Among the aerobic gram-negative organisms, the most common is *Escherichia coli. Klebsiella* sp. and *Proteus* sp. occur in about 5% of genital tract infections. Species that are more resistant to antibiotics, such as *Pseudomonas aeruginosa* and *Enterobacter* sp., occur in approximately 1% or 2% of these cases and are more likely to appear in patients who have previously received antibiotic therapy or who have been hospitalized for some time. Among the anaerobic organisms, the most common gram-positive isolates are *Peptostreptococci* and *Peptococci. Clostridia* sp. occurs less frequently. Among the anaerobic gram-negative organisms, the *Bacteroides* sp. most frequently encountered are *Bacteroides bivius* and *Bacteroides disiens. Bacteroides fragilis* is still a common problem but appears to be less predominent. Other organisms encountered are *Chlamydia trachomatis*, the genital mycoplasmas, yeasts, protozoa, and viruses. (Am J Obstet Gynecol 1987;156:491-5.)

Key words: Genital tract infections, female, microbiology, anaerobes and aerobes, sequelae

Surrounding the bacterial cell is a macromolecular matrix of peptidoglycan, or short strands of peptides cross-linked to a polysaccharide polymer. In gram-positive organisms, this matrix is covalently bound to teichoic acid or teichoglucuronic acid, while in gram-negative organisms, it is bound to the lipoprotein in the outer membrane. New cell walls are developed by the cross-linking of these adjacent peptides, thought to be the sites of β-lactam antibiotic action. This activity against either gram-negative or gram-positive species is dependent on the ability of the β-lactam antibiotic to penetrate through the peptidoglycan matrix and attach to a receptor site. Next, the β-lactam antibiotics must be resistant to β-lactamases and must have an affinity

for the penicillin-binding proteins involved in the synthesis of the bacterial cell wall.

Group B streptococci

The group B streptococci are representative of the aerobic gram-positive cocci. They are isolated in selective media from 5% to 25% of the vaginal cultures of otherwise healthy women. They are commonly involved in maternal and neonatal infections but play less of a role in gynecologic infections. They are involved in endometritis, amnionitis, and neonatal sepsis.

Group B streptococci are encountered in approximately 20% of obstetric infections, and in neonatal sepsis they are one of the most common organisms isolated from the bloodstream.[1] An association has been shown between colonization of the maternal cervix in pregnancy and subsequent adverse outcomes of pregnancy, such as premature rupture of the membranes or premature birth.[2]

The major current problem with group B streptococci is the prediction and prevention of early-onset neonatal sepsis. Even with prompt treatment, the mortality rate is approximately 40%. Boyer et al.[3] have reported using selective intrapartum chemotherapy in women who are colonized with group B streptococci during pregnancy and who have additional risk factors such as premature rupture of the membranes, premature labor, or maternal fever in labor. This treatment has previously been reported to decrease transmission to the neonate and very recently has been reported to significantly decrease group B streptococcal neonatal sepsis.[4]

Group B streptococci are widely susceptible to β-lactam antibiotics, including the penicillins and cephalosporins. Alternative therapy for treating group B streptococcal infection includes erythromycin.

Enterococci

Enterococci are also common gram-positive cocci, the most common being *Streptococcus faecalis*. These are included in the group D streptococci in the Landsfield system. They are isolated from the genital tract of approximately 10% of asymptomatic women. Enterococci are occasionally pathogenic in the heart valve and urinary tract.

During the last decade, the role of enterococci in pelvic infections has been controversial. Isolated from cultures of infected sites in women with endometritis, amnionitis, and postoperative gynecologic infections, they have also been isolated in the bloodstream of women with genital tract infections. Apparently the frequency of isolation of this organism is increasing and it is now found in approximately 25% of the women with postoperative infection after cesarean section.[5] Use of prophylactic cephalosporins appears to be a potent method of increasing the isolation rate of enterococci.[6]

The treatment of choice of *S. faecalis* is a synergistic combination of penicillin plus an aminoglycoside such as gentamicin. In a penicillin-allergic individual, vancomycin may be used as the drug of choice. Patients who have enterococcal urinary tract infections or mild enterococcal infections usually respond well to ampicillin therapy. However, the organism is resistant to penicillin alone, gentamicin alone, and all the cephalosporins including those of the first, second, and third generations, as well as the tetracyclines. When sulbactam is combined with cefoperazone, the 90% minimum inhibitory concentration with enterococci does not decrease markedly.[7]

Staphylococcus aureus

S. aureus is found in the genital tract of approximately 9% to 10% of asymptomatic women, in approximately 10% of patients with postoperative wound abscess after gynecologic or obstetric procedures, and in 5% to 20% of genital tract cultures of women with pelvic infection. It is found in virtually 100% of women who have toxic shock syndrome.[8]

Forty years ago widespread resistance to penicillin G developed in nosocomial isolates of *S. aureus*, and currently 95% of hospital isolates and approximately 85% of community isolates of these organisms produce β-lactamases that confer resistance to penicillin and ampicillin as well as the newer penicillins. Staphylococci are usually susceptible to the β-lactamase–resistant penicillins in the methicillin-nafcillin group, to cephalosporins, and to clindamycin. Methicillin-resistant strains of *S. aureus* have been a problem outside the United States and a relatively infrequent but perhaps growing problem here.

Escherichia coli

E. coli is the most common aerobic gram-negative bacterium in the female pelvis.[9] It is the most common organism isolated from the bloodstream of women who have septic shock complicating pelvic infections.[9] However, it is pathogenic in only 10% to 20% of pelvic infections.[9] This estimate is based on studies with agents such as metronidazole or clindamycin, neither of which are active against *E. coli* or other Enterobacteriaciae.

E. coli and other members of this group are often susceptible to β-lactam antibiotics including several of the newer penicillins and cephalosporins. Aminoglycosides are, however, the drugs of choice.

Several different β-lactamases are detectable in the Enterobacteriaceae group, including *E. coli*. TEM-1 is the most common and accounts for roughly 75% of the β-lactamases produced by this group.[10] These TEM enzymes are plasmid-mediated and constitutive.

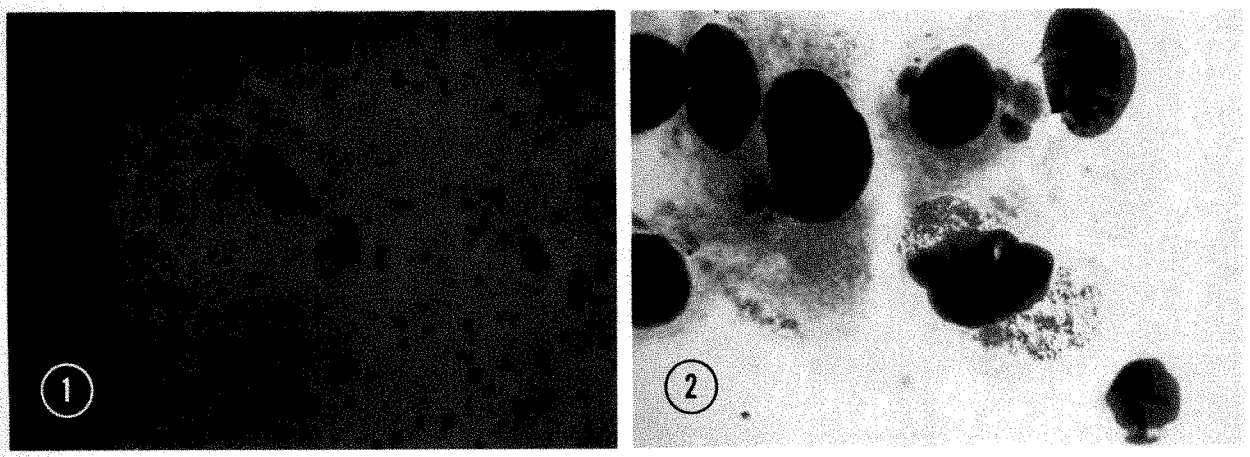

Fig. 1. A culture showing genital mycoplasmas. The larger "fried egg" colonies are *M. hominis*, and the smaller colonies are *U. urealyticum*.

Fig. 2. Tissue culture of *C. trachomatis*. Stain demonstrates *C. trachomatis* inclusions.

Neisseria gonorrhoeae

N. gonorrhoeae is an organism of preeminent importance in pelvic inflammatory disease and may cause disseminated infection, especially in pregnant women. It is isolated in 1% to 25% of cultures depending on the population screened.[11]

Traditionally, *N. gonorrhoeae* has been susceptible to penicillins and other β-lactam antibiotics, as well as to tetracyclines. A little more than a decade ago, however, penicillin-producing strains of *N. gonorrhoeae* were recognized, primarily in the Far East. These strains, however, have remained at a relatively low prevalence in the United States. The β-lactamases responsible for penicillin resistance in *N. gonorrhoeae* are also of the TEM 1 type.

Peptostreptococci

Peptostreptococci are among the most common anaerobic organisms encountered in female genital tract infections and have been isolated, according to recent reports, from 20% to 60% of genital tract cultures.

Peptostreptococci have generally remained widely susceptible to antibiotics, including penicillins, clindamycin, metronidazole, and cephalosporins. Few strains of peptostreptococci have minimum inhibitory concentrations ≥64 μg/ml of penicillin.

Bacteroides bivius

Much information has been gathered concerning the *Bacteroides* sp. isolated from female genital infections. First recognized in 1977, *Bacteroides bivius* is representative of these anaerobic gram-negative bacteria. Several recent studies have determined *B. bivius* to be the most common anaerobe in female genital infections. We find it in approximately 20% of women who have endometritis after cesarean section and in the amniotic fluid of about 20% of women with intra-amniotic infection.[12] In other series it has been isolated in up to 40% of genital tract cultures from women with pelvic infection.

B. bivius is highly susceptible to clindamycin, metronidazole, some of the newer penicillins, and the newer cephalosporins. However, susceptibility to penicillin G is highly variable. Ranges of minimum inhibitory concentrations are broad, and in three susceptibility studies of *B. bivius* the 90% minimum inhibitory concentration values have been 16 to 64 μg/ml.[13-15]

Bacteroides disiens is another recently recognized species found mainly in female genital tract infections. Found in from 2% to approximately 15% of cultures from infected genital tract sites, it has susceptibility patterns similar to those seen with *B. bivius*.[13-15]

Bacteroides fragilis is found in female genital tract infections, but this group is found less commonly than *B. bivius* or *B. disiens* according to recent reports. Approximately 90% of the strains in the *B. fragilis* group produce a constitutive β-lactamase. Agents of choice for treating *B. fragilis* include clindamycin, metronidazole, chloramphenicol, and cefoxitin.

Mycoplasmas

Fig. 1 shows cultures of genital mycoplasmas. *Mycoplasma hominis* is found in 30% to 50% of vaginal cultures of sexually active women, and serologic and blood culture evidence supports a role for this organism in both intrapartum and postpartum infection.[16-18] It is susceptible to tetracyclines and to clindamycin, while β-lactam antibiotics tend to be rather inactive.

The other common genital mycoplasma is *Ureaplasma urealyticum*, being more common in vaginal cultures than *M. hominis*. It is found in 60% to 80% of vaginal cultures of sexually active women. *U. urealyticum* has

been implicated for several decades as a cause of infertility, pregnancy wastage, and premature birth. However, evidence is stronger for the role of *U. urealyticum* in postpartum fever. We have not been able to discern a role for *Ureaplasma* in intra-amniotic infections. Drugs of choice for treating *U. urealyticum* remain tetracycline and erythromycin.

Chlamydia trachomatis

Fig. 2 shows a culture of *C. trachomatis*. It is found in from 2% to 25% of cervical cultures, the wide range being a function of the population. *Chlamydia* is a major cause of acute cervicitis and can cause salpingitis.

Its role in endometritis, however, is less clear. Recent studies from Chicago as well as those from Seattle have implied its role in late-onset, mild endometritis after vaginal delivery.[19, 20] The organism is also an important cause of perinatally acquired infections, neonatal conjunctivitis, and pneumonia.

Agents of choice for treating *Chlamydia* include the tetracyclines, erythromycin, and sulfonamides. Some β-lactam antibiotics, including amoxicillin and ampicillin, have moderate degrees of activity.

Viruses

The viruses that occur commonly in the female genital tract include herpes simplex virus, which has an incidence of less than 1%. Ninety percent of these isolates are of type 2. Cytomegalovirus is most common, being found in some 4% to 15% of the female genital tracts examined. Disseminated infection and viremias from this virus may play an important role in pregnancy infections.

Yeasts

Yeasts are commonly encountered in the genital tract and nearly all are of *Candida* sp. About 95% of all *Candida* sp. found are *Candida albicans*. Approximately 20% of asymptomatic, sexually active women are found to have yeast forms, responsible for about 25% of all cases of vaginitis.[21]

The response rate of these infections is usually good to a variety of compounds including boric acid, gentian violet, and imidazoles. However, the major problem with yeast infections is recurrence and reinfection. Disseminated candidal infections are unusual in otherwise healthy women.

Trichomonas vaginalis

The protozoan encountered commonly in the female genital tract infection is *T. vaginalis*. It is found in approximately 6% to 44% of women.[22] The higher end of the range is usually seen in women attending clinics for sexually transmitted diseases. This organism is responsible for approximately 20% of all infectious vaginitis. The response to treatment with single-dose metronidazole is usually good.[23]

Comment

Many infections of the female genital tract are polymicrobial. Both anaerobes and aerobes have been implicated in these infections. In a rat peritonitis model, organisms of the *E. coli* group, Enterobacteriaceae, contribute to peritonitis, to sepsis, and to death, but it is the anaerobic organisms that contribute to abscess formation.[24]

It has been shown in the rat model, as well as in more recent clinical trials of female patients with genital tract infections, that therapy should be aimed at both the aerobes and anaerobes.[25] The overall response rate will be better, and the likelihood of serious complications such as abscess or septic pelvic thrombophlebitis will be decreased. This was first demonstrated in a study of penicillin and gentamicin compared with clindamycin and gentamicin.[25] The response rate to clindamycin and gentamicin was significantly better and serious complications were decreased.

Single-agent therapy, as with cefoxitin, cefotaxime, moxalactam, and others that have very good activity in vitro against aerobes and anaerobes, has been reported to provide a similar high response rate.[5, 26-28]

A review of the role of β-lactamase–producing bacteria in obstetric-gynecologic infections

David A. Eschenbach, M.D.

Seattle, Washington

β-Lactam antibiotics are the most commonly used antibiotics in obstetrics and gynecology. However, they are susceptible to inactivation when attacked by β-lactamase, an enzyme produced by many bacterial species. During the past three decades, numerous penicillins and cephalosporins have been made with a stable β-lactam ring that resists enzyme attack. More recently enzyme inhibitors have been discovered that inactivate β-lactamase. The combination of an enzyme inhibitor with a β-lactam antibiotic, such as ampicillin, restores the antimicrobial activity of the β-lactam against formerly resistant strains of staphylococci, *Haemophilus influenzae*, Enterobacteriaceae, and *Bacteroides fragilis*. (AM J OBSTET GYNECOL 1987;156:495-503.)

Key words: β-Lactam antibiotic, β-lactamase inhibitor, antibiotic resistance, sulbactam

Recognition of antibiotic resistance began shortly after the introduction of antibiotic therapy in the 1940s and it has become increasingly important today.[1] The rapid and widespread resistance of *Staphylococcus aureus* to penicillin is well documented. Currently more than 95% of *S. aureus* isolates produce β-lactamase enzymes that confer resistance to penicillin and ampicillin. Increasing ampicillin resistance has also been noted for the Enterobacteriaceae including *Escherichia coli*, *Kleb-*

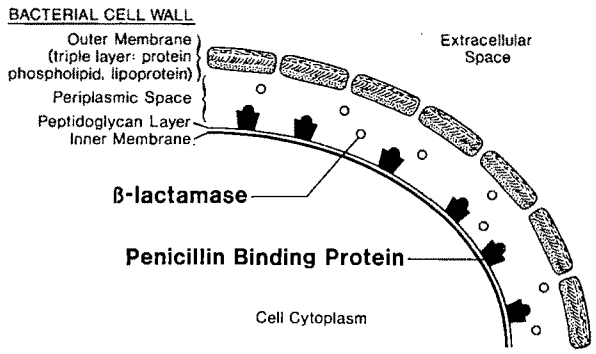

Fig. 1. Schematic representation of gram-negative bacterial cell envelope.

siella pneumoniae, and *Proteus mirabilis.*[2] *Haemophilus influenzae* resistance to ampicillin is now common. *Bacteroides fragilis* and a variety of other *Bacteroides* sp. have long been recognized to be resistant to many penicillins and cephalosporins. The ability of certain organisms to resist the action of β-lactam antibiotics by producing β-lactamase has led to well-documented therapeutic failures to eradicate the organism.[3]

Resistance has generally followed the widespread use of new agents. Some organisms are more able to acquire resistance than others. The most common mechanism of resistance involves bacterial elaboration of antibiotic-inactivating enzymes called β-lactamases. For example, *S. aureus* and Enterobacteriaceae commonly produce β-lactamase that makes them resistant to penicillin. The ability to elaborate β-lactamase enzymes is most commonly acquired when new genetic material is gained by the bacteria through transfer of plasmids from other β-lactamase–producing bacteria.[4] β-Lactamase can also be acquired through random chromosomal mutation of bacteria followed by the selection of resistant organisms through the use of antibiotics.

Other mechanisms of bacterial resistance are present for non–β-lactam antibiotics and, depending on the organism, these other mechanisms of resistance can also inhibit some β-lactam antibiotics. These mechanisms do not involve enzymatic inactivation. Nonenzymatic inactivation of an antibiotic can occur through alteration of the antibiotic target site on the bacterial cell, by blocking antibiotic transport within the bacteria or by bypassing a metabolic step inhibited by the antibiotic. The first two mechanisms change the ability of the drug to reach its site of activity within the bacteria. Examples of this resistance include *S. aureus* resistance to methicillin. A less well-known form of resistance is tolerance, in which organisms that are susceptible to antibiotic inhibition in vitro are still able to tolerate the bactericidal (killing) action of penicillin or cephalosporin.[5] These other mechanisms of resistance will be discussed briefly below to put bacterial resistance in perspective, but the report will emphasize β-lactamase resistance.

Mechanism of action of β-lactam antibiotics

β-Lactam antibiotics are the most widely used antibiotics. They make up more than one third of the top 10 drugs sold in the United States. From 20% to 35% of the typical hospital budget for drugs is spent on cephalosporins alone.[6] They enjoy frequent use both because of their effectiveness and because of their low toxicity. Penicillins, cephalosporins, and cephamycins exert their bactericidal activities by a similar mechanism. These β-lactam antibiotics inhibit bacterial cell wall synthesis, which ultimately produces cell lysis and death.

The basic penicillin nucleus contains a four-membered β-lactam ring attached to a five-membered thiazolidine ring. Penicillin and its derivatives differ in the structures of their side (R) chains. The structure of the basic cephalosporin nucleus contains the same four-membered β-lactam ring as penicillin. However, cephalosporins have a six-membered dihydrothiazide ring attached instead of the thiazolidine ring. Cephalosporins differ in the structures of the two (x and y) side chains.

It is well known that the cell wall is essential for the normal growth and integrity of bacteria. A cross-linked peptidoglycan heteropolymer confers the property of cell wall rigidity necessary for osmotic stability of the bacteria. Penicillin and other β-lactam antibiotics block cell wall synthesis by inhibiting transpeptidase cross-linking, causing weakness of the wall. A combination of mechanical and osmotic instability acts to cause cell death.[7]

However, a critical step that must occur before β-lactam antibiotics are active is the binding of the antibiotic to penicillin-binding proteins (Fig. 1). The antibiotic in the serum reaches the extracellular space between bacteria and it penetrates through pores in the outer membrane of the cell to reach the periplasmic space between the outer and inner cell wall. The inner membrane of the cell surrounds the cytoplasm. Penicillin-binding proteins project into the periplasmic space from their attachment to the inner cell membrane. The β-lactam antibiotic in the periplasmic space must attach to the penicillin-binding protein before inhibition of cell wall synthesis can occur. Inhibition of cell wall synthesis prevents growth of new bacteria and, as previously mentioned, it also causes cell lysis by causing mechanical and osmotic instability.

Cell lysis can also occur directly with higher concentrations of β-lactam antibiotics through activation of cellular autolysins. Although an endogenous intracel-

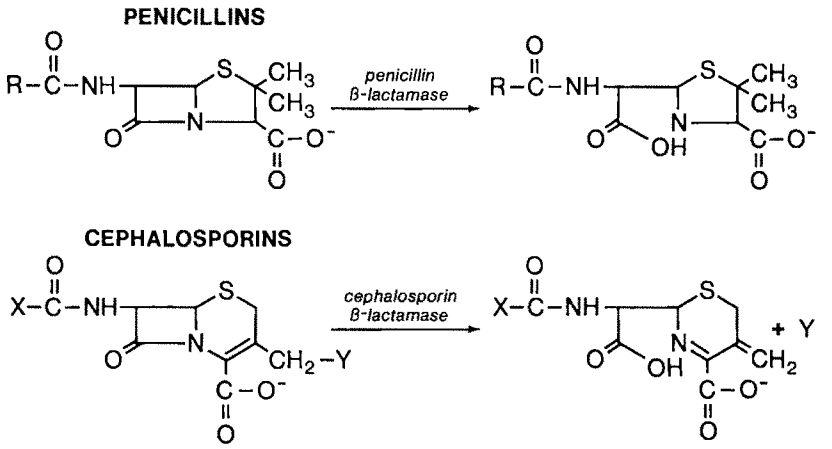

Fig. 2. Action of β-lactamase upon penicillins and cephalosporins, showing the hydrolysis or opening of the β-lactam ring.

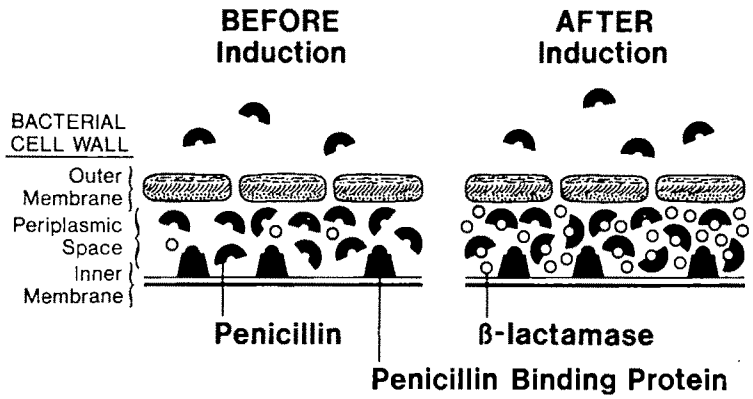

Fig. 3. The presence of β-lactamase in the periplasmic space before and after induction. Greater amounts of β-lactamase result in higher rates of hydrolysis and increased binding of β-lactamase to the β-lactam antibiotic. In both cases less drug is available to bind to penicillin-binding proteins necessary for antibiotic action.

lular inhibitor usually prevents cell destruction by autolysins, β-lactams can allow autolysins to come into contact with their substrates (peptidoglycans), which causes cell lysis and subsequent cell death.[7]

Mechanisms of organism resistance to β-lactamase

There are several mechanisms by which organisms are able to resist the action of β-lactam antibiotics that differ, depending on the antibiotic and the organism. As mentioned, the enzymatic destruction of an antibiotic is the most common and clinically significant manner of antibiotic resistance. Of the three possible enzymes that can potentially inactivate antibiotics—β-lactamase, amidase, and esterase—only β-lactamase is considered to be clinically important. β-Lactamases are present in a wide variety of both gram-positive and gram-negative bacteria. The enzyme irreversibly disrupts the amide bond within the β-lactam ring. Since the β-lactam ring is the crucial site that confers antibacterial activity, opening of the ring causes the antibiotic to lose activity (Fig. 2).

β-Lactamase is located in the periplasmic space between the penicillin-binding protein on the inner membrane and the outer cell membrane. Thus β-lactamases surround the penicillin-binding protein sites. When penicillin penetrates through the outer membrane to reach the periplasmic space, it is susceptible to the action of β-lactamase in the periplasmic space. If β-lactamase is able to disrupt the β-lactam ring before the antibiotic attaches to the penicillin-binding protein site, the antibacterial activity is lost. Once the penicillin has bound to the penicillin-binding protein, however, inhibition of membrane synthesis occurs and the penicillin is able to express its activity. Most of the penicillin can penetrate and bind to the penicillin-binding pro-

teins when small concentrations of enzyme are present in the periplasmic space. However, increased concentrations of enzyme can result if the antibiotic itself induces further production of β-lactamase. Some of the β-lactam antibiotics have the unfortunate property of inducing the production of β-lactamase in a number of organisms. A high level of β-lactamase allows the enzyme to destroy the antibiotic before attachment to penicillin-binding protein can occur (Fig. 3). It should be mentioned that, although penicillin is usually destroyed, in a newly described mechanism β-lactamase can also bind to the antibiotic without destruction of the penicillin itself.[8]

Several organisms have developed a high level of resistance to β-lactam antibiotics through the production of β-lactamase. Highly resistant gram-positive organisms include *S. aureus* and more recently, *Staphylococcus epidermidis.* Highly resistant gram-negative organisms include *Pseudomonas, Klebsiella,* and *Enterobacter* and *Bacteroides* sp., most frequently *B. fragilis, Bacteroides bivius,* and *Bacteroides disiens.* Both *H. influenzae* and, more recently, *Neisseria gonorrhoeae* have also developed the ability to produce β-lactamase. A wide variety of other species produce β-lactamase less commonly.

There are other, less important mechanisms that do not involve β-lactamase in which the activity of β-lactam antibiotics is reduced. A loss of activity occurring from reduced entry of the antibiotic into the microorganism is recognized to be particularly important for gram-negative bacteria. Gram-negative organisms have a more complex outer membrane than gram-positive organisms. The phospholipid in the outer membrane of gram-negative bacteria acts as a hydrophobic barrier that reduces the penetration of β-lactam antibiotics through the outer membrane pores (Fig. 1). Alterations of the penicillin-binding proteins that prevent penicillin attachment have also been proposed as a mechanism of reducing the action of penicillin but there is limited evidence for this hypothesis at present.

Classification of β-lactamases

Various β-lactamase classification systems have been proposed to assist and clarify enzyme research. To date, β-lactamases have been classified by substrate and inhibitor profiles, isoelectric point focusing, immunogenic activity, molecular weight, and genetic origin. The Richmond-Sykes classification system[9] originally described β-lactamases on the basis of substrate profiles, but this system was later modified by Sykes and Matthew[10] to combine these profiles with genetic control (Table I). β-Lactamase production can be either chromosomally or plasmid mediated.

Chromosomally mediated β-lactamases occur in most

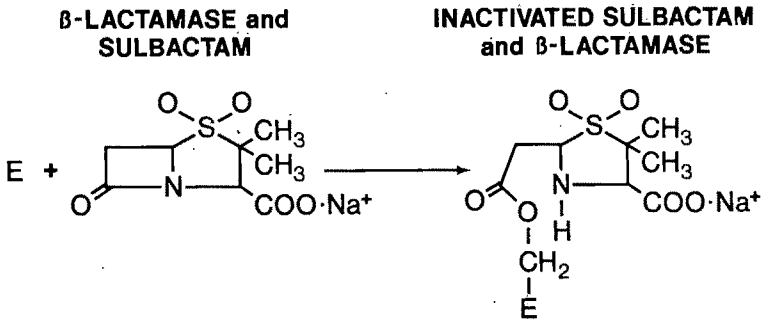

Fig. 4. Interaction of sulbactam, an irreversible β-lactamase inhibitor, with β-lactamases showing lethal action of sulbactam preventing regeneration of the enzyme and further hydrolysis.

organisms. The level of enzyme produced by chromosomal control is quite variable and ranges from barely detectable to high even in the absence of antibiotics. Increased β-lactamase production can occur either through spontaneous chromosomal mutation or by enzyme induction, a phenomenon that is increased by the presence of antibiotics. Penicillinase (Type II), cephalosporinase (Type I), and enzymes that hydrolyze both penicillin and cephalosporin (Type IV) are produced by chromosomally mediated genetic control. Type II penicillinase is present in *S. aureus, Proteus* sp. and *Pseudomonas* sp. It is inhibited by isoxazolyl penicillins, such as cloxacillin, and by β-lactamase inhibitors discussed below, sulbactam and clavulanic acid (Table I). Type I cephalosporinases are found in Enterobacteriaceae and they are inhibited by isoxazolyl penicillins and carbenicillin but not by clavulanic acid. Type IV β-lactamases that equally hydrolyze penicillins and cephalosporins are present in certain Enterobacteriaceae and they are inhibited by sulbactam and clavulanic acid.

Plasmids are extrachromosomal pieces of deoxyribonucleic acid that can be carried by bacteria. The extra genetic material is commonly transferred from one bacterium to another. Genetic information in the transferred plasma can be expressed if the material is incorporated into the host cell chromosome. If the plasmid deoxyribonucleic acid carries a code for antibiotic resistance (R plasmid), the host bacteria will develop resistance to that antibiotic or antibiotics. Plasmid-mediated resistance is of greater importance than chromosomally mediated resistance since it is more common in nature and it often confers resistance to multiple antibiotics at one time. Two categories of R-plasmid–mediated β-lactamases exist. One includes Type III β-lactamases that are active against both penicillins and cephalosporins. These enzymes are the most important of the β-lactamases because they are the most common. They are present in virtually all Enterobacteriaceae. Of the more than 10 Type III β-lactamases, the single most ubiquitous is present in 77% of Enterobacteriaceae. This enzyme is inhibited by cloxacillin, clavulanic acid, and sulbactam (Table I). Type V β-lactamase is also plasmid mediated with a profile similar to that of Type III. Type V is produced by *E. coli* and *Pseudomonas* sp. Type VI β-lactamase is produced by *Bacteroides*. The activity of this enzyme is inhibited by the isoxazolyl penicillins, clavulanic acid, and sulbactam (Table I).

Methods to reduce antibiotic resistance

There are several mechanisms to reduce or reverse antibiotic resistance. One successful method has been the formulation of β-lactamase–stable antibiotics. Broad-spectrum penicillins (ampicillin, amoxicillin, azlocillin, carbenicillin, mezlocillin, piperacillin, and ticarcillin) and the extended-spectrum cephalosporins (cefoxitin, cefamandole, moxalactam, cefotaxime, cefoperazone, cefotetan, etc.) are able to resist the action of one or more β-lactamases. The β-lactam rings of the broad-spectrum penicillins and extended-spectrum cephalosporins are hydrolyzed at a much lower rate than penicillin G or cephalothin. An example of the slower rate of hydrolysis of cefamandole, cefotaxime, moxalactam, and cefoxitin compared with that of cephalothin is provided in Table II.[11] The resistance to β-lactamase hydrolysis allows these extended-spectrum β-lactam antibiotics to maintain their antimicrobial activity despite the presence of enzymes.

A new method to reduce antibiotic resistance involves the combination of a β-lactamase inhibitor with a β-lactam antibiotic. There are several types of β-lactamase inhibitors. Sulbactam and clavulanic acid are two β-lactamase inhibitors that are termed suicide inhibitors because they irreversibly inactivate β-lactamases.[12] An example of the sulbactam reaction with β-lactamase *(E)* is provided in Fig. 4. A temporary, inactive β-lactamase–sulbactam complex is formed before the production of a stable, inactivated β-lactamase–sulbactam complex. The irreversible binding of these compounds to the active site of the β-lactamase inhibits the enzyme. Both the inhibitor and the enzyme are then irreversibly destroyed. The inhibitors themselves have virtually no inherent antibacterial activity. Therefore β-lactamase inhibitors are combined with a β-lactam antibiotic. The inhibitor destroys the β-lactamase, effectively restoring the antimicrobial activity of the antibiotic, which would

Table III. Minimum inhibitory concentration of ampicillin alone and combined with sulbactam or clavulanic acid

Organism	Geometric minimum inhibitory concentration (μg/ml)		
	Ampicillin alone	*Ampicillin with sulbactam, 5 μg/ml*	*Ampicillin with clavulanic acid, 5 μg/ml*

Other *Bacteroides* spp. (n = 46)	32	4	8	2	4

Modified from Wexler et al.[4]

otherwise be impaired by the enzyme. The result is a combination with greater antibacterial activity than that of the antibiotic alone. This increase in antibacterial activity varies, depending on the antibiotic and the inhibitor.

The role of these inhibitors in combination with a β-lactam antibiotic has been investigated in inhibition studies, in vitro susceptibility studies, and in vivo. Table III shows an example of the reduction of the minimum inhibitory concentration needed to inhibit organisms when sulbactam or clavulanic acid is combined with ampicillin. The minimum inhibitory concentration of various organisms to ampicillin alone is consistently higher (the antibiotic is less active) than the minimum inhibitory concentration of the organism to the combination of ampicillin-sulbactam or ampicillin–clavulanic acid. The addition of sulbactam or clavulanic acid to ampicillin increased the activity of that antibiotic.[13]

This is demonstrated in Table IV, where the 90% minimum inhibitory concentration of three different *Bacteroides* species is compared for ampicillin, chloramphenicol, clindamycin, metronidazole, and the combination of ampicillin-sulbactam. A total of 272 strains of anaerobic bacteria were tested.[14] Ampicillin-sulbactam was significantly more effective against *B. fragilis* and the other *Bacteroides* sp. than ampicillin alone. While the addition of β-lactamase inhibitors increases the activity of ampicillin, amoxicillin, ticarcillin, or cephalothin, β-lactamase inhibitors do not enhance the activity of all β-lactam antibiotics. The addition of β-lactamase inhibitors does little to enhance the activity of the newer, β-lactamase–stable antibiotics cefamandole, cefotaxime, moxalactam, or cefoxitin.[15]

Frequency of β-lactamase–producing bacteria in a review of obstetric-gynecologic infection

Thirty-six reports of infections in obstetrics and gynecology published between 1973 and 1986[16-51] were selected. Also included were 84 patients with postpartum endometritis at the University of Washington, in whom cultures were obtained as previously described[50] but the results have not yet been reported. In all reports, modern culture methods were used to recover organisms from infected areas. Enough patients had to be enrolled to provide a valid sample and the cultures had to be obtained from sites that are considered to be sterile in the uninfected patient. Organisms were isolated from the endometrium of women with postpartum endometritis[19-24, 26, 27, 32, 33, 40, 49, 50]; the cul-de-sac, abdomen, or tubes from women with acute pelvic inflammatory disease[43-48]; blood from patients with a wide variety of infections[17, 28-30, 35, 40, 41]; and wound and abscesses of women who had gynecologic operation.[31, 36] A final category in which the various infected sites could not be separated was also included (mixed infection).[16, 18, 25, 34, 37, 39, 42]

The isolates reported in these studies were coded into a software program in which 29 individual aerobic spe-

cies, 18 individual anaerobic species, genital mycoplasmas, *Chlamydia trachomatis, Trichomonas vaginalis,* and *Candida* sp. were recorded. The bacterial species were then further divided into those isolates highly likely to produce β-lactamase (+), those isolates that have variable β-lactamase activity (±), and isolates that have a low prevalence of β-lactamase activity (−). It is emphasized that actual β-lactamase production was not reported in any of these studies and an estimate of the prevalence of β-lactamase activity was derived from in vitro data. No estimate was attempted of the concentration of β-lactamase that might be expected from the organisms. The organisms were then stratified according to expected high, variable, and low β-lactamase activity as shown in Table V. Infections occurred in a total of 2687 individuals in these 36 studies. A total of 6637 bacterial species were recovered at a rate of 2.5 organisms per patient.

A consistent prevalence of organisms in the three β-lactamase categories was demonstrated by the wide variety of obstetric and gynecologic infections listed. Facultative and anerobic gram-positive isolates and anaerobic gram-negative isolates in particular were recovered at similar rates in all of the infected sites. Enterobacteriaceae were less commonly isolated from the tubes–abdomen–cul-de-sac of women with acute pelvic inflammatory disease than from other infections. Enterobacteriaceae were also more frequently reported from the blood or abscesses than from other sites.

S. aureus, a frequent β-lactamase producer, accounted for 2% of the total isolates. *S. epidermidis,* a variable β-lactamase producer, accounted for 5% of isolates. Other facultative streptococci and other gram-positive organisms accounted for approximately 28% of total isolates. As mentioned, the proportion of isolates in these categories was consistent between infected sites. Enterobacteriaceae (in order of their frequency: *E. coli, Proteus mirabilis, Klebsiella* sp., *Enterobacter* sp., and *Citrobacter* sp.) and *Pseudomonas* sp. accounted for 13% of all isolates. Virtually all Enterobacteriaceae produce β-lactamase. *N. gonorrhoeae* and *Gardnerella vaginalis* each accounted for about 2.5% of the total isolates. These two organisms only infrequently produce β-lactamase.

Two frequent β-lactamase–producing gram-negative anaerobic bacteria, *B. bivius* (3.9%) and *B. fragilis* (3.6%), together were present in more than 7% of the total organisms isolated. Other *Bacteroides* sp., including *Bacteroides melaninogenicus,* that variably produce β-lactamase were found in 10% of the total isolates. Anaerobes that infrequently produce β-lactamase accounted for the remaining 29% of isolates.

In a summary of these findings, organisms expected to frequently produce β-lactamase were present among 1483 (22%) of the total 6637 isolates obtained from obstetric-gynecologic infections. An additional 15% of the total organisms isolated would be expected to variably produce β-lactamase. The proportion of potential β-lactamase–producing organisms showed only minimal variability among the various infected sites (Table VI). Although a mean of 2.5 organisms were isolated per patient, most of the patients would be expected to have only one of the β-lactamase producers. The actual number of patients who had more than one β-lactamase producer could not be determined from the data provided in these studies. From these data, it can be estimated that 20% to 30% of the obstetric and gynecologic infections contained organisms that produce β-lactamase.

The high proportion of β-lactamase–producing organisms in obstetric-gynecologic infections can have several consequences. One is the immediate resistance of the infecting organism to β-lactam antibiotics. The effectiveness of β-lactamase–stable antibiotics in the treatment of obstetric-gynecologic infections has become widely recognized. The use of new β-lactamase inhibitors such as sulbactam or clavulanic acid in combination with β-lactam antibiotics should also be useful in providing further resistance against β-lactamase and improving treatment results. Further experience with these new combinations is necessary.

The recovery of certain, less virulent β-lactamase–producing organisms such as *S. epidermidis* from infected upper genital tract sites has often not been considered particularly significant. However, the production of β-lactamase by one organism may potentially reduce the effective local β-lactam antibiotic level enough to influence successful therapy. In the throat, β-lactamase production by normal mouth flora reduces the rate of successful group A streptococci eradication by penicillin.[52] The failure of penicillin to consistently eliminate *N. gonorrhoeae* from the rectum has been attributed to the production of β-lactamase by rectal flora. Thus β-lactamase production by organisms of seemingly low virulence in the upper genital tract could theoretically be a cause of failure of antibiotic therapy to eradicate otherwise sensitive organisms from the upper tract. In addition, β-lactamase production by normal vaginal flora has not been studied, but it could be an explanation for the inability of ampicillin to eradicate group B streptococci from lower genital tract sites. Another possibility, particularly after antibiotic prophylaxis, is that vaginal β-lactamase production contributes to the selection of a wide variety of organisms, including those that do not produce β-lactamase. The persistence of one virulent organism in the vagina because of protection from another nonvirulent but β-lactamase–producing organism could contribute flora that subsequently causes upper tract infection. This circumstance would be particularly likely after cesarean section or prophylaxis associated with gynecologic operations.

An increase in the number of β-lactamase–producing organisms has been noted among women who have failure of therapy, and at least one fourth of patients can be expected to have infections that require treatment with antibiotics that are resistant to β-lactamases.[24, 35] Many obstetric-gynecologic infections involve β-lactamase–producing organisms. The use of newer broad-spectrum penicillins and cephalosporins has resulted in a higher cure rate compared with that of antibiotic regimens that do not contain β-lactamase–stable agents.[55] The combination therapy with β-lactamase inhibitors and β-lactam antibiotics should also result in high cure rates. It is now necessary to initiate treatment of most obstetric and gynecologic infections with either β-lactamase–stable antibiotics or the combination of β-lactamase inhibitors and a β-lactam antibiotic.

Induction of β-lactamase enzymes: Clinical applications for the obstetric-gynecologic patient

David L. Hemsell, M.D.
Dallas, Texas

The emergence of bacteria resistant to antibiotics has resulted in intensive research for new and improved β-lactam antibiotics. Many improvements in antimicrobial agents are based on a knowledge of the mechanism responsible for resistance. This has led to the development of new extended-spectrum antibiotic compounds. However, several features have been noted since the development of extended-spectrum antibiotics, such as the rapid development of bacterial resistance, the induction of β-lactamase enzyme activity by these stable antibiotics, failure to detect induced enzyme activity and resistance in the laboratory, and β-lactam antagonism. The resistance of bacteria to antimicrobial agents has obvious impact on the selection of appropriate therapy against infections caused by these pathogens. Gram-negative anaerobic bacteria, such as *Bacteroides fragilis* and *Bacteroides bivius*, are organisms frequently recovered from women whose initial therapy for pelvic infection failed. The transfer of antimicrobial resistance in bacteria indicates that these organisms have a system for the spread of such resistance. Therefore determination of antimicrobial susceptibilities and prompt eradication of isolates from infected patients are necessary to delay the emergence of resistant organisms. (AM J OBSTET GYNECOL 1987;156:504-6.)

Key words: β-Lactam antibiotic, antibiotic resistance, induction, antagonism

Before the introduction of penicillin in 1941, Abraham and Chain[1] had reported the observation that an enzyme produced by *Escherichia coli* prevented the bactericidal activity of benzylpenicillin. There has been a rapid expansion of the β-lactam technology during the past 45 years. The intensive search for new and improved β-lactam antibiotics has arisen because of the development of resistance to antibiotics in the clinical setting.

Three variables impact on the ability of bacteria to develop antibiotic resistance, including alterations in the structure or affinity of penicillin-binding proteins, alterations to cell membrane permeability, and production of β-lactamase enzymes. Current drug research has been aimed at developing β-lactam antibiotics that are resistant to the principal means of antimicrobial inactivation by bacteria—the production of β-lactamase enzymes.

β-Lactamase enzyme production

The production of β-lactamase in bacteria may be mediated through extra chromosomal genetic information, termed R factors or plasmids, or it can be chromosomally mediated. Most β-lactamase production is plasmid mediated rather than chromosomally mediated.[2] There are, however, several bacteria that possess a chromosomally mediated ability to dramatically increase the production of β-lactamase after exposure to an inducer, the principal inducers being the β-lactam antibiotics.

β-Lactamase activity sites vary among the different bacteria. In gram-negative bacteria, the predominant β-lactamase activity occurs within the inner and outer cell wall membranes in the periplasmic space. For gram-positive bacteria such as *Staphylococcus aureus*, the β-lactamase exerts its activity extracellularly. Several β-lactamases have been identified in gram-negative aerobic bacteria. The Richmond and Sykes classification system[2] was developed to categorize these enzymes.

Class I enzymes are chromosomally mediated and have cephalosporins as their primary substrate. The genetic expression of these enzymes is that they are inducible. The clinical pathogens in which they are seen are the gram-negative aerobic pathogens *Enterobacter, Citrobacter, Serratia* and *Proteus* sp., and *Pseudomonas aeruginosa*.

Class II β-lactamases are clinically rare and have penicillins as their primary substrate. They are chromosomally mediated and constitutive, or produced at a constant rate.

The principal gram-negative β-lactamase enzyme observed in bacteria recovered from the obstetric and gynecologic patient population is in the Class III category. The substrates for these enzymes are both pen-

icillins and cephalosporins, and the enzyme is produced constitutively. These enzymes are plasmid mediated and account for approximately 85% of β-lactamases observed. The clinical pathogens secreting these enzymes are *Neisseria gonorrhoeae, Haemophilus influenzae, Pseudomonas aeruginosa,* and various species in the Enterobacteriaceae family.

Class IV β-lactamases are active against both penicillins and cephalosporins and are chromosomally mediated. They are constitutive and are seen uncommonly, primarily in *Klebsiella* sp.

Class V enzymes are effective against penicillins, cephalosporins, and isoxazolyl penicillins. This class constitutes the remaining 15% of the plasmid-mediated β-lactamase production. This enzyme is also constitutive and is found primarily in *Pseudomonas* sp. and in species of the Enterobacteriaceae family.

The β-lactamase secreted by gram-positive aerobic bacteria is effective primarily against penicillins and is inducible. It has been observed in both *Staphylococcus aureus* and *Staphylococcus epidermidis.*

β-Lactam antibiotics

Several of the β-lactam antibiotics, including the penicillin and ampicillin families and the first-generation cephalosporins, are generally susceptible to β-lactamase. The enzyme binds to and hydrolyzes the β-lactam ring, thus rendering the antimicrobial ineffective. The ineffective metabolite is released, and the β-lactamase that is still active inactivates another antimicrobial molecule.

Current research has been aimed at the development of antimicrobials that are β-lactamase stable. Some of these newer antibiotics include methicillin, nafcillin, the oxacillins, second- and third-generation cephalosporins, penems, and thienamycin. While it was believed that these newer antibiotics would resist enzymatic degradation, induction of β-lactamase enzyme activity by these enzyme-stable antibiotics has recently been observed.[3]

β-Lactamase induction

Recent studies have demonstrated that bacteria possessing inducible β-lactamases may develop resistance to a variety of β-lactam antibiotics. It appears that the enzyme induced in bacteria is either reversible, if the inducer is a β-lactam antibiotic, or irreversible, if overproduction of the enzyme occurs as a result of mutation. The β-lactamase enzyme, once induced, renders the strain resistant to many β-lactam antibiotics, including the newer, more stable compounds that are not hydrolyzed by the enzymes. Enzyme-antimicrobial binding does occur, but it is nonhydrolytic, which apparently acts as a stimulus to dramatically increase the production of β-lactamase enzyme. When mutation occurs, resistance to a multiplicity of antibiotics in specific organisms or bacteria is observed.

Enzyme inducer activity

Primary research has involved exposure of certain bacteria to various antibiotics in order to establish an inducer profile. One such study using *Enterobacter cloacae* demonstrated that low inducers, that is, the antibiotics that do not stimulate bacteria to increase their production of β-lactamase enzyme, are methicillin, piperacillin, and cefoperazone.[4] Intermediate inducers observed were carbenicillin, cefotaxime, and cefuroxime and high inducers included cefazolin, cephalothin, cefamandole, cefoxitin, moxalactam, and clavulanic acid.

These results identify a problem with the enzyme-induction concept since, theoretically, the antibiotic that is resistant to the hydrolytic activity of the β-lactamase should be the inducer. Contrariwise, those that serve as a good substrate for hydrolytic activity and are destroyed should not be high inducers of enzyme production. Additionally, this phenomenon may be strain-dependent. In another study that added further confounding data, induction of β-lactamase was studied in an *E. cloacae* strain isolated from a clinical specimen.[5] Large amounts of the enzyme were induced in the presence of β-lactams. In this study, cefoxitin and mezlocillin were low inducers, while penicillin and moxalactam were high inducers. Other cyclic structures may also induce enzyme activity; these include folic acid, hemin, trypticase soy broth, human serum, pleural fluid, cerebrospinal fluid, and Schaedler's broth. Cefoxitin was most potent as an inducer in trypticase soy broth.

The importance of the induction of β-lactamase enzymes in clinical medicine is unknown. This phenomenon has been observed in the laboratory in bacteria recovered from patients whose antibiotic therapy was successful or unsuccessful. The identification of this phenomenon does not therefore imply clinical relevance.

Detection of induced enzyme activity is relatively difficult to identify in the laboratory. Microdilution and disk diffusion techniques do not identify induction until after it has become clinically evident. The clinical manifestation of enzyme induction is either a failure to respond to therapy or the development of a superinfection. Enzyme induction in the laboratory, however, can be confirmed with the macrodilution technique and use of an inoculum of $\geq 10^5$ cfu/ml of organisms.

Another distressing phenomenon that has been observed is that of β-lactam antagonism. The potential for antagonism between some of the newer β-lactam antibiotics lies in the ability of the enzyme-stable antibiotics to act as inducers of β-lactamase. The drug-

induced enzyme hydrolyzes or creates a barrier against access to target proteins.

Antagonism has been observed specifically with cefoxitin both in vivo and in vitro.[6] It is seen when cefoxitin and other β-lactam antibiotics are combined and administered for an infection caused by bacteria with the inducible enzyme system. It is also seen clinically when a β-lactam antibiotic is given as pretreatment or prophylaxis or when treatment is given with subinhibitory dosing. Research in this field indicates that it is the responsibility of the microbiologist to identify the bacteria mentioned above, bacteria that have the potential for inducing the production of β-lactamase, and to inform the physician so that he or she can find alternative therapy to the β-lactam antimicrobials should there be evidence of clinical failure.

Consequences for the obstetric-gynecologic patient

Most obstetric and gynecologic patients do not develop pelvic infections caused by organisms in which β-lactamase enzyme induction is a problem. However, there does seem to be increasing antibiotic resistance because of several factors, including prolonged antimicrobial prophylaxis, that may accelerate the problem of altered resistance patterns, in addition to induced resistance.

Ampicillin/sulbactam versus metronidazole-gentamicin in the treatment of soft tissue pelvic infections

William R. Crombleholme, M.D., Marilyn Ohm-Smith, Marilyn O. Robbie, Vicki DeKay, and Richard L. Sweet, M.D.

San Francisco, California

The clinical efficacy and safety of ampicillin/sulbactam versus metronidazole-gentamicin were evaluated in a comparative, randomized, prospective study. Forty-four patients were enrolled: 22 received the ampicillin/sulbactam regimen, and 22 received the metronidazole-gentamicin combination. There were 33 cases of severe acute pelvic inflammatory disease, two tuboovarian abscesses, five cases of endomyometritis, and two cases of posthysterectomy pelvic cellulitis. Aerobic and anaerobic cultures from the infection sites yielded 447 microorganisms from 44 patients (an average of 10 bacteria per infection; 6.4 anaerobes and 3.7 aerobes). The most frequent isolates were *Bacteroides sp.*, 54; *Bacteroides bivius*, 17; black-pigmented *Bacteroides*, 12; *Bacteroides disiens*, 11; *Fusobacterium*, 13; *Peptostreptococcus anaerobius*, 24; *Peptostreptococcus asaccharolyticus*, 21; anaerobic gram-positive cocci, 34; *Gardnerella vaginalis*, 29; *Neisseria gonorrhoeae*, 17; α-hemolytic streptococci, 15; and *Escherichia coli*, five. Clinical cure was noted in 19 of 20 patients treated with ampicillin/sulbactam and 18 of 21 patients treated with metronidazole-gentamicin. One treatment failure occurred in the ampicillin/sulbactam group in a patient who required antichlamydial therapy and had a complex left adnexal mass consistent with an abscess. The cases of metronidazole-gentamicin failure included two patients initially diagnosed as having tuboovarian abscesses who required a change in antibiotic therapy to control the infections. The third patient had postabortion endomyometritis that did not respond to metronidazole-gentamicin therapy within 48 hours, and required a change of medication. No adverse hematologic, renal, or hepatic effects were noted in either group of patients. (Am J Obstet Gynecol 1987;156:507-12.)

Key words: Pelvic infections, sulbactam, ampicillin, gentamicin, metronidazole

Although an array of antimicrobial agents are currently available today, soft tissue pelvic infections continue to be a major cause of morbidity in obstetric and gynecologic patients.[1] The most common soft tissue pelvic infections diagnosed in a gynecologic-obstetric service include posthysterectomy pelvic cellulitis, vaginal cuff abscess, pelvic abscess, pelvic inflammatory disease, tuboovarian abscess, post–cesarean section infection, endomyometritis, septic abortion, and septic pelvic thrombophlebitis.[2]

The pathogens responsible for soft tissue pelvic infections include a wide variety of aerobic and anaerobic organisms. The aerobic organisms include *Escherichia coli*, group B streptococci, and other facultative streptococci. The anaerobic organisms include: *Bacteroides bivius*, other *Bacteroides*, and *peptostreptococci*. Of the several underlying causes and characteristics of these infections, two are of particular importance. First, many of the organisms responsible for obstetric and gynecologic infections (with the exception of *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and group A streptococci) arise from the normal flora of the lower genital tract. Second, many of these infections have a "polymicrobial etiology"[3,4]; that is, these infections are due to multiple organisms including mixtures of anaerobes and aerobic organisms or mixtures of anaerobic bacteria.

Study results accumulated during the last 5 years have underscored the importance of initial antimicrobial therapy aimed at eradicating resistant anaerobes, particularly *Bacteroides*.[2,5-7] Several studies have examined the effectiveness of single-agent and multiple-agent therapies including clindamycin-aminoglycoside, metronidazole-aminoglycoside, and, more recently, such combinations as clindamycin-aztreonam.[8,9] Several single-agent regimens have been shown prospectively to be fairly effective in treating mixed pelvic infections.[10-12] These agents include second- and third-generation cephalosporins, the extended-spectrum penicillins, and some of the newer cephalosporin-related compounds.

An alternative option to the treatment of mixed anaerobic-aerobic infections associated with resistant β-lactamase enzyme–producing bacteria has been suggested. This approach entails the use of a β-lactamase

enzyme inhibitor combined with an available β-lactam antimicrobial agent such as ampicillin, amoxicillin, or ticarcillin. The result is an enhanced spectrum of activity against β-lactamase enzyme–producing bacteria, including *E. coli, B. bivius,* and penicillinase-producing *N. gonorrhoeae.*

The randomized, prospective study reported herein was designed to evaluate the safety and efficacy of the combination therapy ampicillin/sulbactam as compared with metronidazole-gentamicin in the treatment of mixed aerobic and anaerobic soft tissue pelvic infections.

Material and methods

The study was conducted in hospitalized women 18 years of age or older, at San Francisco General Hospital, San Francisco, California, with a documented or clinical diagnosis of mixed aerobic-anaerobic pelvic infection. Excluded from the study were pregnant or lactating women; patients who were allergic to penicillins, cephalosporins, aminoglycosides, or metronidazole; those with impaired renal function (serum creatinine >1.8 mg/100 ml); those with a family history of glycogen storage disease or recurrent hypoglycemia; or those with a history of unstable cardiovascular, hepatic, renal, or neurological disease.

The patients underwent a series of pretreatment laboratory tests which served as baseline values and were repeated every 4 days. These tests included complete blood count with differential and platelet counts, total bilirubin, serum glutamic oxaloacetic transaminase, serum glutamic pyruvic transaminase, alkaline phosphatase, direct Coombs test, serum creatinine, urinalysis, serum pregnancy test by the β-subunit of human chorionic gonadotropin (on admission), and hepatitis B surface antigen (on admission). Blood specimens were taken and cultured for anaerobic and facultative organisms on admission before the start of antibiotic therapy. Cervical cultures were performed only for *N. gonorrhoeae* and *C. trachomatis.* Endometrial brush samples were taken with a double-lumen catheter and the specimens were cultured for *N. gonorrhoeae, C. trachomatis, Mycoplasma hominis,* and *Ureaplasma urealyticum,* as well as for anaerobic and facultative organisms by means of methods previously described.[14] Culdocentesis was performed to obtain peritoneal fluid in patients with posthysterectomy cuff cellulitis. Isolates were tested for β-lactamase production using discs (Cefinase, BBL, Cockeysville, Maryland).

Patients were then randomized prospectively to receive one of two antibiotic regimens. The ampicillin/sulbactam (A/S) group received ampicillin, 2 gm, and sulbactam, 1 gm, intravenously every 6 hours. The metronidazole-gentamicin (M-G) group received metronidazole, 15 mg/kg intravenously as a loading dose, then 7.5 mg/kg intravenously every 6 hours in combination with gentamicin, 1.5 mg/kg intravenously every 8 hours. Therapy continued until patients became afebrile and were without clinical signs of infection for 48 hours or until clinical judgment dictated cessation of therapy. Generally the antibiotics were administered for at least 5 days.

Forty-four patients were enrolled in the study, half in the A/S group and half in the M-G group. The A/S group included 14 patients with acute pelvic inflammatory disease, two with tuboovarian abscesses, four with endomyometritis, and two with posthysterectomy pelvic infections. The M-G group included 19 patients with pelvic inflammatory disease, one with tuboovarian abscess, one with endomyometritis, and one with posthysterectomy infection.

Patient population. The 44 patients in this study were representative of the general clinic patient population at San Francisco General Hospital (Table I). Demographically the patients in both groups were similar with respect to age, racial background, gravidity, and parity. Clinically the patients were also similar. The A/S group had a slightly lower mean white blood cell count, 10.8 compared with 13.0 in the M-G group. Duration of therapy was also similar in both groups, 5.2 versus 5.7 days.

Pretreatment cultures. The results of the direct plate and broth cultures were typical for what might be expected in patients with soft tissue pelvic infections, that is, a large number of mixed aerobic and anaerobic organisms, particularly *Bacteroides.* Table II shows the

aerobic isolates from pretreatment cultures. The gram-positive organisms included primarily *Staphylococcus epidermidis* and hemolytic and nonhemolytic streptococci. *N. gonorrhoeae* was the most commonly encountered gram-negative organism. *Gardnerella vaginalis* was also frequently cultured, although mainly in primary plates rather than broth cultures. Table III lists the anaerobic isolates from the pretreatment cultures. The most common gram-positive organisms cultured were *peptostreptococci,* including *Peptostreptococcus asaccharolyticus, Peptostreptococcus anaerobius,* and *Peptostreptococcus tetradius.* The *Bacteroides* were the most common gram-negative anaerobes cultured. *B. bivius* was the most frequent isolate of the gram-negative anaerobes cultured. Also commonly seen were *Bacteroides disiens, Bacteroides capillosus,* and black-pigmented *Bacteroides.* Of particular interest is the finding in four patients of *Mobiluncus* sp. isolated from the upper genital tract. In addition, *M. hominis* was commonly isolated, while *Ureaplasma urealyticum* was not. *C. trachomatis* was also isolated from patients with pelvic inflammatory disease.

Results

Table IV shows the clinical response of those patients receiving the A/S regimen and those receiving the M-G regimen. One patient in the A/S group with a clinical diagnosis of pelvic inflammatory disease and a right adnexal mass was excluded. Laparoscopy revealed a right ovarian cyst, no visual evidence of infection, and essentially no growth from cervical and endometrial cultures. One patient in the M-G group with a clinical diagnosis of pelvic inflammatory disease was excluded; she left the hospital against medical advice on the third hospital day. Clinical cure was defined as a response to the antimicrobial combination alone without the need for surgical intervention or additional therapeutic agents. A/S proved to be as effective as M-G in treating mixed aerobic and anaerobic soft tissue pelvic infections in our groups of patients. In the 21 patients who completed treatment in the A/S group, clinical cure was demonstrated in 16 (76%) and in 16 of the 21 in the M-G group. Another three patients (14%) in the A/S group and two (9%) in the M-G group demonstrated clinical cure after doxycycline was added to the regimen to treat chlamydial infections. When these subsets are combined, the A/S group demonstrated a 90% cure rate compared with an 85% clinical cure rate in the M-G group.

One patient in the A/S group was considered to be a clinical failure because she developed an allergic reaction and had to stop taking the medication. There were no allergic reactions in the patients receiving M-G. One additional patient in the A/S group and three in the M-G group were considered to be treatment failures. The patient in the A/S group had acute pelvic inflammatory disease and did not respond to A/S treatment within 3 days. Results of a sonographic examination showed a complex cystic mass in the left adnexa, which may have been present at the time of admission but was obscured by peritoneal and pelvic tenderness. Antibiotic therapy was changed to tobramycin plus clindamycin and the patient responded. Among the three treatment failures in the M-G group, two patients had pelvic inflammatory disease and a tuboovarian abscess.

Table IV. Clinical response with A/S regimen and M-G regimen

	A/S (N = 21)		M-G (N = 21)	
	n	%	*n*	%
Clinical cure	16	76	16	76
Clinical cure plus doxycycline	3	14	2	9
Failure (secondary to drug reaction)	1	5	0	0
Clinical failure	1	5	3	14

When the first patient had not responded to therapy within 3 days, a sonographic examination showed a cystic mass in the right adnexa. Clindamycin was added to the treatment regimen. The condition of the patient, however, did not improve and she underwent a unilateral salpingectomy. The second patient had bilateral tuboovarian masses and improved only after receiving clindamycin. The third patient had postabortal endomyometritis and was given cefoxitin after she had not responded to the M-G regimen within 48 hours. The infection was cured; however, analysis of laboratory results showed no reason why she had not responded to the initial medication.

Adverse reactions. A/S appeared to be better tolerated than M-G in this patient population. There were no adverse hematologic, renal, or hepatic side effects noted in either group. Four (18%) of the patients in the A/S group, compared with one (4.5%) of the patients in the M-G group, experienced some pruritus. However, eight (36%) patients in the M-G group experienced nausea and/or vomiting, compared with only two (9%) patients in the A/S group.

Microbiologic isolates. Eradication of the organisms isolated before treatment was better with the A/S combination than with M-G (Table V). The A/S regimen appeared to eradicate almost all of the organisms cultured. After treatment, only nine positive primary plate cultures were obtained from the endometrial cavity, as compared with 153 positive pretreatment cultures. However, after treatment with M-G, 55 positive pri-

Table VI. Minimum inhibitory concentrations of bacteria isolated from pretreatment cultures

Organism	Ampicillin		A/S		Metronidazole	
	MIC_{50}	MIC_{90}	MIC_{50}	MIC_{90}	MIC_{50}	MIC_{90}
Black-pigmented *Bacteroides* sp. (n = 10*)	0.06	128.0	0.125	2.0	2.0	2.0
B. bivius (n = 17)	16.0	64.0	2.0	4.0	4.0	8.0
B. capillosus (n = 6)	8.0	8.0	1.0	1.0	2.0	4.0
B. disiens (n = 12)	0.5	8.0	0.25	1.0	4.0	8.0
B. fragilis group (n = 3)	16.0	16.0	1.0	2.0	1.0	2.0
Bacteroides sp. (n = 32)	0.5	32.0	0.25	1.0	2.0	8.0
Fusobacterium sp. (n = 8)	0.06	0.06	0.06	0.06	0.06	0.25
Mobiluncus (n = 4)	0.06	0.06	0.06	0.06	2.0	4.0

MIC_{50} = 50% minimum inhibitory concentration; MIC_{90} = 90% minimum inhibitory concentration.
*Number of isolates.

mary plate cultures were obtained from the endometrial cavity, compared with 132 before treatment. The organisms most frequently cultured after treatment were gram-positive and gram-negative aerobes. The failure to eradicate the organisms from primary plate cultures did not correlate with clinical failure or clinical response.

Minimum inhibitory concentration determinations were evaluated on bacteria isolated from pretreatment cultures. Ampicillin alone would have been ineffective against the major organisms responsible for the soft tissue pelvic infections in these patients, particularly *Bacteroides*. The addition of sulbactam lowered the minimum inhibitory concentrations and the A/S combination appeared to be more effective in vitro than metronidazole alone (Table VI). For example, the A/S combination reduced the minimum inhibitory concentration against black-pigmented *Bacteroides* from 128.0 with ampicillin alone to 2.0 with A/S. Similarly, the minimum inhibitory concentration against *B. bivius* was reduced from 64 to 4.0. The minimum inhibitory concentrations of metronidazole against black-pigmented *Bacteroides* and *B. bivius*, respectively, were 2.0 and 8.0. No significant enhancement of ampicillin by sulbactam against other non-*Bacteroides* organisms was seen.

Table VII. β-Lactamase production among *Bacteroides* isolates recovered from study patients

B. bivius	16	1
B. capillosus	4	2
B. disiens	8	3
Bacteroides sp.	20	16
Total	55	28

Comment

Study results demonstrated that A/S is as effective as M-G in treating mixed aerobic-anaerobic pelvic infections. Moreover, the A/S combination appeared to be better tolerated than the M-G combination. It is important to recognize that metronidazole-aminoglycoside regimens will not be effective against some of the major pathogens responsible for pelvic infections, including chlamydia, group B streptococci, and other facultative streptococci. In addition, our study found that two thirds of the *Bacteroides* found in female genital tract infections were β-lactamase producers, against which ampicillin alone is ineffective.

Table VII shows β-lactamase production among the *Bacteroides* isolates recovered from our patients. Fifty-five (66%) of the 83 *Bacteroides* isolates cultured from the upper genital tracts of patients were β-lactamase producers. Five (50%) of the black-pigmented *Bacteroides* isolates were β-lactamase producers. Strikingly, 16 of 17 (94%) *B. bivius* organisms isolated from pelvic infections were β-lactamase producers. Similarly, 70% of the *B. capillosus* and *B. disiens* isolates were β-lactamase producers. More than half of the *Bacteroides* sp. thought to be sensitive to penicillin and first-generation cephalosporins were in fact β-lactamase producers. Without the use of the enzyme blocker sulbactam, ampicillin alone would have been ineffective in treating two thirds of the infections seen in these patients. Clearly, results of this study point out the need to include antimicrobial agents that are either resistant to β-lactamase or contain irreversible enzyme blockers against β-lactamase production.

The recovery of *Mobiluncus* sp. from the upper genital tract of patients with pelvic inflammatory disease is intriguing. *Mobiluncus* sp. have been implicated in bacterial vaginosis (formerly nonspecific vaginitis) as a component of the complex synergistic milieu of microorganisms involved in this entity, including *G. vaginalis,* anaerobic bacteria, α-hemolytic streptococci, and *M. hominis.*[15] Eschenbach[16] postulated that bacterial vaginosis may well be an antecedent precursor of acute pelvic inflammatory disease, especially the nongonococcal, nonchlamydial type. This hypothesis requires further investigation.

Infectious morbidity in gynecologic cancer

Doris C. Brooker, M.D., John E. Savage, M.D., Leo B. Twiggs, M.D., Leon L. Adcock, M.D., Konald A. Prem, M.D., and Christine C. Sanders, Ph.D.

Minneapolis, Minnesota, and Omaha, Nebraska

A retrospective investigation of infectious morbidity in gynecologic oncology patients documented that 54 (11%) of 494 patients and 68 (6%) of 1204 patient admissions were complicated by a serious infection. The highest rate of infectious morbidity by admission was 21%, occurring in patients admitted for cancer of the vulva. The highest surgical infectious morbidity, 22%, occurred in patients admitted for cervical cancer. Important factors in determining infection risk include multiple host factors, radical surgical procedures, factors inherent in the tumor itself, and additional irradiation and chemotherapy. These serious polymicrobial infections dictate intelligent selection of antimicrobials and appropriate monitoring to anticipate complications inherent in antimicrobial therapy. β-Lactamase induction, superinfection, nephrotoxicity, and necrotizing enterocolitis are documented problems in these patients. (Am J Obstet Gynecol 1987;156:513-20.)

Key words: Infectious morbidity, gynecologic cancer, genital tract malignancy

Malignancy of the female genital tract is an important and costly determinant in women's health care today. In 1986, cancer of the breast and lung will account for an estimated 18% and 19%, respectively, of cancer deaths in women.[1] Deaths from cancer of the uterus and ovary will total 4% and 5%, respectively. The incidence of cancer differs from the above mortality statistics. Breast malignancy accounts for 26% of all female cancer; cancers of the lung and uterus each have an incidence of 11%, and cancer of the ovary, 4%.

These figures reflect in part the stage at which malignancies are first recognized. Cancers of the cervix and uterus are diagnosed earlier, at a local stage of disease 44% and 78% of the time, respectively. In contrast, 49% of breast and 67% of lung malignancies are diagnosed after regional and distant spread has occurred in the patient. With the epidemiologic tools of the Papanicolaou smear, endometrial biopsy, and aggressive management of uterine bleeding and enlargement, the uterine cancer death rate has seen a steady decline since 1940. Deaths from breast and ovarian malignancy have remained fairly constant, but deaths from lung cancer have been rising at a logarithmic rate since 1970.

Infectious morbidity-mortality in gynecologic oncology has not been the subject of extensive investigation. An understanding of the basis of these infections requires an understanding of the multiple infection risk factors in the host, those in the extended radical surgical procedures, and factors inherent in the tumor itself.

Host factors include: (1) normal vaginal flora; (2) altered flora and organism virulence in malignancy; (3) altered flora from previous use of antimicrobials including induction of antimicrobial resistance and superinfection[2-7]; (4) general host defense factors such as mucosal barriers, cellular and humoral immunity, and normal and decreased neutrophil, lymphocyte, and macrophage function; (5) known surgical risk factors in women with malignancy such as older age, poor nutritional status (weight loss, obesity), and concurrent disease such as diabetes, hypertension, and bacterial or viral sexually transmitted disease; (6) previous host chemotherapy and/or radiation therapy.[8]

Risks derived from the radical surgical procedure include: (1) prolonged time of operation with the increased dissection and tissue damage of the extended "radical" procedure and presence of blood and exudate in the operative site and (2) anesthesia risk.[9-11]

The major risks arising from the tumor itself are: (1) preexisting subclinical infections in proliferating and necrotic malignancy and (2) possible immunosuppressive effects exerted by the tumor itself.[12-22]

In addition to the usual risks deriving from host factors, from the surgical procedures, and from the tumor itself, invasive diagnostic techniques used before operation add to the risk from the possibility of preexisting occult infection of the genital tissue and possible introduction of nosocomial infection. Invasive procedures such as cystoscopy, proctoscopy, needle biopsy, and dilatation and curettage are routine as are ma-

nipulative radiographic procedures such as intravenous pyelography, upper gastrointestinal series, barium enema, computerized axial tomographic scan, and ultrasound.

Finally, modern supportive procedures that add to postoperative infection risk include ureteral catheterization, percutaneous nephrostomy, central venous catheterization, hyperalimentation, and use of Jackson-Pratt drainage tubes, as well as urethral catheterization, insertion of a nasogastric tube, and placement of an intravenous line, all of which are common in patients after operation.[13, 14]

Given the lack of statistics in infectious morbidity and mortality in gynecologic malignancy, a retrospective descriptive investigation of the University of Minnesota Gynecologic Oncology Service was conducted for the year 1982 (January 1 through December 31, inclusive). Each admission was thoroughly examined for evidence of infection as well as the level of significance of infection. The infection was then correlated with the individual patient's malignancy, irradiation therapy, chemotherapy, surgery, and various other factors. The overall objective of the investigation was not only to compile a statistical file of infectious morbidity and mortality but also to use this file to develop specific and useful guidelines for prevention of infectious risk and

for intelligent selection of antimicrobials. Ultimately these guidelines are to be put to use in prospective evaluations that lead to improved patient management.

The following discussion is a limited presentation of the 1982 investigation and is divided into three sections: first, general oncology data; second, infectious morbidity and mortality by cancer type, including general infection statistics, specific host factor analysis, and microbiology as well as serious infection by therapy mode; and third, the complications of antimicrobial therapy (Table I).

General oncology data

John L. McElvey Oncology Registry. The John L. McElvey Oncology Registry was created in the early 1940s and has maintained women's cancer statistics at the University of Minnesota without interruption since that time. In 1982, the Registry recorded 259 newly diagnosed malignancies, including 95 of the cervix, 73 of the uterus, 26 of the vulva, and 55 of the ovary. There were five new cases each of primary vaginal and gestational trophoblast disease.

Admissions by cancer site and therapy mode. There were a total of 1204 admissions to the service, including 436 (36%) for ovarian, 325 (27%) for cervical, 268 (22%) for uterine, 48 (4%) for vulvar, and 5% for other female genital malignancy. In addition, 66 (5%) admissions were for conditions other than malignancy. Of these 1204 admissions, 454 (38%) were for chemotherapy, 331 (27%) for operation, 173 (15%) for radiation therapy, and 93 (8%) for combinations of any of the above indications. Twelve percent of the admis-

sions involved evaluation only, with no therapeutic procedure.

Infectious morbidity and mortality

Serious infections by cancer type. A total of 494 individual patients accounted for the 1204 admissions. Fifty-four patients (11%) had a serious infection diagnosed during an admission. Ten patients had multiple admissions for the same infection (68 admissions for the 54 patients). Thus 6% (68 of 1204) of total admissions were complicated by serious infection (Table II). Uncomplicated urinary tract infections are not included in this tally.

There were 325 admissions for cancer of the cervix, and 26 (8%) of these were complicated by an infection. There were 268 admissions for uterine cancer, and 18 (7%) of these involved an infection. Three percent (12 of 436) of admissions for ovarian cancer were complicated by infection. Infectious morbidity for vulvar cancer was 21% (10 of 48) and for other female genital malignancy, 3% (two of 61) (Table III).

There were a total of 239 surgical procedures performed in 1982: 73 surgical procedures for cervical cancer (including 26 staging laparotomies, 21 radical hysterectomies, and two pelvic exenterations) and 58 surgical procedures for uterine malignancy (including 46 abdominal hysterectomies and one pelvic exenteration). Twenty-two percent (16 of 73) of cervical cancer patients had an infection complicating the admission for operation. Similarly, 12% (seven of 58) of uterine cancer patients, 11% (six of 55) of ovarian cancer patients, 12% (five of 42) of vulvar cancer patients, and 18% (two of 11) of patients with other gynecologic malignancy had an infection complicating the admission for operation (Table IV).

Host factor analysis. Selected characteristics of this patient population that contributed to the risk of serious infection included patient age, length of stay, and stage of disease (by International Federation of Gynecology and Obstetrics). The larger number of patients and admissions were for cervical and uterine cancer. As expected, vulvar, uterine, and ovarian cancer occurred more frequently in the older population (Table V).

The average length of stay (Table VI) for vulvar can-

Urinary tract infection	*K. pneumoniae* *E. coli* Enterococci

cer patients far exceeded that of any other malignancy and accounted for the longest hospital stay. In the FIGO staging analysis (Tables VII to X), one of the most significant risk factors for infection was advanced stage of malignancy. More than 50% of cervical and uterine cancer patients had FIGO Stage II, III, or IV disease. The risk was even more pronounced in ovarian and vulvar cancer admissions, in which 85% had FIGO Stage III or IV disease.

Host factor analysis of mortality data (Table XI) showed that the eight patients who died during an admission all had FIGO Stage III or IV disease. Four of the eight died during an admission in which an operation-related infection occurred. However, all of the patients had other, more important complicating factors (myelosuppression, cardiomyopathy, advanced malignancy) that contributed to death.

Microbiology. The types of surgical infection found in gynecologic malignancy are shown in Tables XII to XV. These infections were typically polymicrobial, including both facultative gram-positive and gram-negative organisms as well as abundant anaerobes. The most likely source of these organisms was the altered vaginal flora.

Organisms such as *Pseudomonas, Enterobacter,* enterococci, *Candida, Clostridia,* and *Bacteroides* were frequently isolated in cases of significant infection (septicemia, pelvic cellulitis and hematoma, peritonitis, pneumonia, and pelvic abscess). In treating infections in which organism identification is not yet known, one must use empiric therapy that will cover this serious spectrum of organisms and anticipate the possible complications that may arise from such therapy.

During 1982 and 1983, in an investigation blinded to the evaluator, 13 gynecologic oncology patients with serious postoperative infections were prospectively randomized to netilmicin-clindamycin (N-C) or cefotaxime (C) therapy. All six N-C–treated patients responded promptly to treatment, while five of seven C-treated patients did not improve ($p = 0.02$). The investigation was terminated because single-agent therapy did not appear to treat these serious gynecologic infections effectively, especially in abscesses and deep tissue infections.

Infection risk by therapy mode. The risk of infection from operation and irradiation therapy was greatest in cervical (23 of 25) and uterine (21 of 30) cancer (Tables XVI and XVII). Chemotherapy was used more frequently in ovarian cancer patients than in cervical and uterine cancer patients. Chemotherapy and operation were almost equal risks for infection in ovarian cancer patients (Table XVIII). For vulvar cancer patients, operation posed the greatest risk (Table XIX). Recrudescence of *Herpesvirus,* a known risk in irradiation and chemotherapy, occurred in two of the 54 infected patients.

Complications of antimicrobial therapy

Several selected cases that highlight complications of antimicrobial therapy in gynecologic cancer patients are presented here. Complications discussed include: (1) antimicrobial resistance (β-lactamase induction), (2) organism selection (superinfection), (3) nephrotoxicity, and (4) necrotizing enterocolitis.

Case presentations

Case No. 1: β-Lactamase induction and antimicrobial resistance. The patient, a 74-year-old diabetic woman, had undergone radical vulvectomy and bilateral inguinal lymph node dissection. After operation, she developed a wound infection and urinary tract infection. She shared a whirlpool bath with patients from a nearby unit caring for burn patients. She was given 11 days of third-generation cephalosporin therapy.

Among other organisms, a type-specific *P. aeruginosa* was present in both groin wound infections and in the urinary tract infection. Initially sensitive to the cephalosporin, organisms became multiply resistant while the patient was receiving therapy. The β-lactamase inactivated the semisynthetic penicillins as well as multiple third-generation cephalosporins (Table XX). The inducible β-lactamase became constitutively produced (Table XXI). The emergence of multiple β-lactam resistance of the *Pseudomonas* in this patient was due to the in vivo selection of a mutant that was derepressed for β-lactamase production. Resistance mediated by this β-lactamase is via hydrolysis of substrate drugs and the nonhydrolytic barrier mechanism for poor or nonsubstrate drugs.[23, 24] Superinfection with yeast and enterococci also occurred during therapy.

Case No. 2: Organism selection and superinfection. The patient, an 83-year-old woman, had recurrent retroperitoneal low-grade leiomyosarcoma (primary in 1964) as well as pulmonary and cardiac disease. She underwent exploratory laparotomy and debulking of malignancy. She became febrile (temperature of 102.4° F) after 8 days of second-generation cephalosporin therapy.

Subclavian catheter tip and blood cultures taken at the febrile episode grew *S. epidermidis* and *E. aerogenes*. After treatment with tobramycin and vancomycin she became afebrile. A diagnosis of endocarditis was considered because cardiac and neurological compromise was evident, but the previous history of cardiac and pulmonary disease made definitive diagnosis difficult. Tobramycin and vancomycin were discontinued. She received another 8 days of second-generation cepha-

losporin therapy. She again became febrile with a temperature to 103° F. The patient had a urinary tract infection with *P. mirabilis*. Blood culture grew *S. epidermidis* and enterococci. The subclavian catheter tip grew *E. aerogenes, S. epidermidis,* and *P. mirabilis*. With ampicillin therapy, she became afebrile.

The antimicrobials were discontinued, and the patient again became febrile (temperature to 101.2° F). Blood culture grew enterococci; the subclavian catheter tip grew enterococci and *E. aerogenes*. At this time, there was evidence of valvular thickening, and the diagnosis of endocarditis was confirmed. The patient was begun on a regimen of long-term penicillin-gentamicin therapy.

Case No. 3: Nephrotoxicity. The patient, a 26-year-old woman, had squamous cell cancer of the cervix, FIGO Stage IV, diagnosed at the original operative pro-

cedure. She underwent exploratory laparotomy and colostomy. Previously she had undergone abdominal and pelvic irradiation and cisplatin chemotherapy. She developed a subphrenic abscess after operation and was treated with aminoglycoside. During therapy, she developed documented aminoglycoside nephrotoxicity that was reversible when antimicrobial therapy was discontinued.

Case No. 4: Nephrotoxicity. The patient, a 61-year-old diabetic woman, had adenocarcinoma of the endometrium, FIGO Stage IB. Total abdominal hysterectomy and bilateral salpingo-oophorectomy were performed with subsequent pelvic irradiation. She developed *K. pneumoniae* septicemia from an infected lymphocyst. One week after completion of aminoglycoside therapy, she developed reversible nephrotoxicity. Renal function returned to normal in 1 month.

Case No. 5: Necrotizing enterocolitis. The patient, a 77-year-old woman, had adenocarcinoma of the endometrium (FIGO, Stage IA), melanoma, and right hypernephroma. She underwent total abdominal hysterectomy, bilateral salpingo-oophorectomy, and right radical nephrectomy. Second-generation cephalosporin therapy was given for a total of 7 days after operation.

The first postoperative complication consisted of interstitial nephritis and renal failure induced by the cephalosporin and reversible on discontinuation of the antimicrobial. The second complication was diarrhea secondary to necrotizing enterocolitis. Toxicogenic *C. difficile* and its toxin were identified in the stool. The patient was given vancomycin, and the infection resolved. She then developed a urinary tract infection, from which *P. aeruginosa* was isolated. This infection resolved with semi-synthetic penicillin therapy.

Comment

Serious infections are a frequent occurrence in gynecologic oncology patients. Intelligent selection and appropriate monitoring of antimicrobial therapy are vital in preventing complications, which can include β-lactamase induction, superinfection, nephrotoxicity, and necrotizing enterocolitis.

We wish to thank Loretta Leman and Anne Shepard for consistent research data collection and evaluation throughout this project.

CORRESPONDENCE

Surveillance of twin pregnancy with umbilical arterial velocimetry

To the Editors:

We read with interest the paper by Farmakides et al. (AM J OBSTET GYNECOL 1985;153:789-92) in which they report their results of umbilical artery Doppler studies in twin pregnancies.

Farmakides et al. conclude that the twin fetus of average for gestational age has elevated umbilical vascular resistance compared to the singleton fetus. We have not found this to be the case in our study using the same technique nor did Giles et al.[1] in their study of twin pregnancy.

This discrepancy can be explained by the fact that Farmakides et al. categorized their fetuses as being of average or small for gestational age by means of inappropriate criteria. They used data from Naeye[2] which was collected solely from twins who were stillborn or died in the first week of life. As many as 30% of perinatal deaths in twins result from intrauterine growth retardation and asphyxia; thus the mean birth weight in Naeye's population is considerably less than is usually recorded for twins and therefore cannot be used to determine whether a twin fetus is average or small for gestational age.

Their average for gestational age population would include a number of fetuses that would be considered small for gestational age by singleton criteria, and this explains both the apparent low incidence of growth-retarded fetuses (10%) and the elevated systolic/diastolic ratio in their average for gestational age population.

Reply

To the Editors:

We appreciate the continuing interest of Ritchie and McCowan in our work. We also look forward to the publication of their data so that we can compare differences in results.

As indicated in their letter, since our results apparently differ from those of Giles et al., Ritchie and McCowan offer the suggestion that our choice of weight standards may explain the differences. They may be right, but as they are well aware, there is no general agreement about which standard to use for either a single or twin fetus when defining growth retardation.

There are many other reasons for differences in results. In addition to the choice of weight standards, one could add (1) statistical methods, (2) use of Doppler device, (3) use of spectrum analyzer, (4) choice of subjects, and (5) size of sample just to mention a few.

The road to truth is a tortuous one. This is a new area of investigation. Our study is a beginning. The essential point is that Doppler velocimetry will identify the twin fetus at risk for death or damage from inadequate umbilical flow. This is a valuable addition to our surveillance methodology. The exact numbers will be revealed from continuing study of more women.

Additional statistical analysis of antenatal phenobarbital for prevention of neonatal intracerebral hemorrhage

To the Editors:

We read with interest the report by Shankaran et al. (AM J OBSTET GYNECOL 1986;154:53-7) regarding the prevention of intraventricular hemorrhage with antenatal phenobarbital. We would like to question one of the statistical conclusions and then to offer some additional analysis.

In column 1 of page 55 they say, "Among infants who developed intracerebral hemorrhage, significantly more control infants were delivered vaginally." Examination of the data reveals the following: of the 13 control infants who had hemorrhage, seven were delivered vaginally and six nonvaginally; of the eight treated infants with hemorrhage, two were delivered vaginally and six nonvaginally (Fisher's exact test, $p = 0.201$). We wonder if the intended assertion was, "Of infants delivered vaginally, significantly more control infants developed hemorrhage." Examination of the data concerning that statement reveals the following: of 13 control infants delivered vaginally, seven had hemorrhage and six did not; of 14 treated infants delivered vaginally, two had hemorrhage and 12 did not ($p = 0.037$).

Detailed statistical analysis was not presented on mechanical ventilation as a confounding variable. Of 32 infants ventilated, 20 developed some form of hemorrhage; of 16 infants not ventilated, only one had some form of hemorrhage ($p = 0.0007$, χ^2). Of control infants who hemorrhaged, it appears that those who were mechanically ventilated may have had significantly more moderate/severe hemorrhage compared to those

who were not ventilated ($0.47 < p < 0.096$, Fisher's exact test; the precise value could not be determined from the data presented). The degree of mechanical ventilation and severity of respiratory distress are also impossible to factor from the data presented.

These issues aside, the fact still remains that there was a significant difference in the number of moderate/severe hemorrhages between those infants whose mothers received phenobarbital and those who did not. This difference was present despite serum phenobarbital levels well below the "anticonvulsant levels" used by Donn et al.[1] and Morgan et al.[2] Donn et al. found a decreased incidence of grade I and II hemorrhages in infants treated postnatally with phenobarbital. Morgan et al. found no differences in either mild or severe hemorrhage after postnatal administration of phenobarbital. We wonder whether the effect seen with antenatal phenobarbital administration is due to effects on labor patterns (frequency, force, and duration of contractions) and not directly on the infant. Future studies in which the labor history is more completely documented might help clarify this issue. Inclusion of data regarding the use of tocolytics and steroids would also be beneficial.

We applaud the authors for their work and certainly agree that further prospective randomized trials of antenatal phenobarbital should be carried out.

Reply

To the Editors:

We thank Dr. Jarrett for his careful review of our paper and for correcting our error on column 1 of page 55. Of the 13 control infants who were delivered vaginally, seven developed hemorrhage while six did not, and among the 14 treated infants delivered vaginally, two developed hemorrhage and 12 did not ($p < 0.05$). Hence the intended assertion was "Of the infants delivered vaginally, significantly more control infants developed hemorrhage." The vaginal mode of delivery has been shown to be a risk factor for hemorrhage by other investigators.

We have done more analysis of the relation between mechanical ventilation and the degree of hemorrhage in the control and treated groups of infants (see Table I). When evaluating the infants who did not require mechanical ventilation, we found no significant difference in the incidence of hemorrhage versus no hemorrhage or no and mild hemorrhage versus moderate and severe hemorrhage between the control and the treated groups of infants. On the other hand, when we evaluated infants who required mechanical ventilation, there was a significant difference in the incidence of intraventricular hemorrhage between the treated and control infants when comparing no hemorrhage versus hemorrhage ($p = 0.02$) and no and mild hemorrhage versus moderate and severe hemorrhage ($p = 0.003$). Hence phenobarbital was not protective among the nonventilated group (who had a very low incidence of hemorrhage) but was protective against moderate and severe hemorrhage in the ventilated group. Infants requiring mechanical ventilation have been shown to be at a great risk for intraventricular hemorrhage.

We can only speculate on the mode of action of antenatal phenobarbital administered in the 500 mg dose. The levels achieved were lower than those used in all other studies evaluating the effects of postnatal phenobarbital therapy and were not associated with any complications. We are in the second phase of our study and are evaluating the effects of phenobarbital on labor patterns, as well as the effect of tocolytics and β-methasone on incidence of intraventricular hemorrhage. We thank Dr. Jarrett for his helpful suggestions.

Intrapartum fetal heart rate monitoring

To the Editors:

In their randomized controlled trial of continuous electronic versus intermittent auscultatory fetal heart rate monitoring during labor (AM J OBSTET GYNECOL 1986;152:524-39), MacDonald and his colleagues from the National Perinatal Epidemiology Unit have suggested that continuous electronic monitoring is superior in reducing the incidence of seizures in the neonate. They deserve our congratulations and gratitude for undertaking so large a trial and "policing" it so well; and I hope I am not being merely curmudgeonly in pointing out what seems to me an important flaw in their opus magnum.

For a randomized controlled trial to be utterly convincing, it needs to be more than large and well conducted. It must also stimulate confidence that both groups of patients were treated with the same will and determination to achieve the best possible results for the patients in them. In the recent Dublin trial the very protocol for the management of the intermittent auscultation group ensures that maximal results for the patients in this group were impossible to achieve. Arguably, the best sign of fetal distress that can be detected by intermittent auscultation is slow recovery of the fetal heart rate after contractions and this entails auscultating the fetal heart rate by Pinard stethoscope (or Doppler ultrasound, if necessary) both during and after contractions. I was taught this during my first resident obstetric job over 20 years ago, and it remains routine practice with the midwives in the units with which I am currently associated. By insisting in their protocol that the fetal heart rate be auscultated "following a contraction" or during the "interval between contractions," the Dublin workers have ensured that this major sign of fetal distress will have been missed until severe and prolonged enough to present as a profound baseline bradycardia. This single and simple fact could account for the very low incidences of fetal heart rate abnormality requiring electronic monitoring (0.49%) or fetal blood sampling (0.6%) in the intermittent auscultation group, the longer duration of labor in this group, and the higher incidence of neonatal seizures.

I wonder if MacDonald et al. have considered this severe limitation to the practical value of their work?

D. D. Mathews, M.D.
All Saints' Hospital
Chatham, Kent, England ME4 5NG

Reply

To the Editors:

Dr. Mathews believes that the method of intermittent auscultation of the fetal heart which he uses is superior to the method evaluated in the Dublin randomized trial. We have also heard that other obstetricians believe that their methods of interpreting fetal heart rate traces are superior to those evaluated in the trial. These beliefs should be seen for what they are: clinical opinions that cannot (so far) be supported with evidence from properly controlled clinical experiments.

Dr. Mathews has already tested the validity of a number of his beliefs in other areas of obstetric practice by mounting randomized trials.[1-6] We hope that he and others who believe that more effective methods of intrapartum fetal monitoring exist than those compared in the Dublin trial will apply similar scientific self-discipline in respect of these beliefs.

Transcervical chorionic villus sampling

To the Editors:

We feel obliged to respond to the article entitled "A randomized study of three cannulas for transcervical chorionic villus sampling" (MacKenzie et al. AM J OBSTET GYNECOL 1986;154:34-9) because it presents the Portex catheter as an ineffective sampling device. (Incidentally, in Fig. 1 the picture of the Portex Trophocan is incomplete and only shows the obturator—the catheter itself is missing).

The Portex catheter is the instrument used in most of the centers reporting to the World Health Organization Registry.[1] This shows that in nearly 12,000 diagnostic cases performed at 90 centers worldwide, there has been an overall rate of failure of diagnosis of 2.6% and a maximum fetal loss rate of 4%, falling to <2% at experienced centers. Most of the samples have been taken for karyotyping.

By contrast, Mackenzie et al. achieved only a 60% success rate in obtaining a sample of villous material and only a 16% success rate in obtaining a karyotype with use of the Portex catheter.

The discrepancy between the experiences of the authors and the rest of the world is probably due to differences in technique; for instance, it appears that they do not inspect the sample for the presence of an adequate amount of chorionic villi at the bedside. This inspection is necessary for the rapid feedback required to perfect the obstetrician's skill and to maintain a high rate of sampling success[2] and is a nearly universal feature of diagnostic sampling procedures.

A second objective of the study was to simplify the procedure by having one operator perform both the scanning and the sampling, but this issue has already been competently addressed by Rodeck et al.[3] in 1983.

We all recognize that there are problems associated with transcervical chorionic villus sampling, and the development of the transabdominal route is one that we support.[4]

It seems likely that the authors' difficulties could have been resolved in the conventional way by discussion with scientific colleagues. It is a pity to resort instead to designing yet more sampling devices and publishing a report that, to the reader who does not actually practice chorionic villus sampling, seriously misrepresents the current state of the art.

Reply

To the Editors:

We are grateful for the interest shown by Ward et al. in our article.

At no point do we claim that it is impossible to obtain chorionic villi with a high degree of success with use of a Portex cannula in the diagnostic situation. It is always possible to obtain villi given the right set of circumstances with use of practically any cannula. The point of this study was to determine whether by applying a certain defined set of circumstances in a randomized manner to each of three different cannulas there was any detectable variation in the weight of villus and the number of successful karyotypes obtained.

The technique followed was exactly that recommended in the leaflet that accompanied the Portex Trophocan device. Before the study one of the authors had performed biopsies in a large series of patients with use of the Portex, so that experience with the technique was deemed to be adequate.

The main criticisms leveled at the authors seem to be (1) that the sample obtained was not inspected for an adequate amount of villi at the bedside and (2) that "difficulties" could have been resolved by discussion with scientific colleages. We would like to reply to these points.

First, each sample was inspected for the presence of an adequate amount of chorionic villi at the bedside. Such an inspection does not invalidate the results, however, since the number of passes made with each catheter had already been decided before each sampling and the presence or absence of villi could have no effect on this. In other words, the results were not permitted to bias the manner of the experimentation.

Second, when diagnostic samples are being undertaken the authors do "address their problems in the conventional way." The outcome of a visit to King's College Hospital was a modification in the suction procedure which we believe would have improved the yield of villi obtained.

Consequently in our diagnostic series of patients receiving biopsies by transcervical chorionic villus sampling with use of an aluminum cannula, the success rate in obtaining a karyotype by means of direct preparations of these samples is 100%.

Thus our point still stands that under direct comparable circumstances when the limiting factor is the type of cannula employed, the aluminum type proved to give the most satisfactory results.

MATERNAL-FETAL MEDICINE

Berkshire Medical Center
Pittsfield, Massachusetts

A rapidly growing Perinatal Program is recruiting a second full time faculty subspecialist in Maternal-Fetal Medicine effective July 1, 1987. Responsibilities include consultations and care of high-risk patients, genetic counseling and testing, level II ultrasound, resident and student teaching.

Berkshire Medical Center is a 365-bed Regional Referral Medical School and a major teaching center affiliated with the University of Massachusetts. The position provides an excellent opportunity to develop a state-of-the-art program in Maternal-Fetal Medicine in a suburban setting. Competitive salary arrangement.

If you are board eligible or certified in Maternal-Fetal Medicine, contact: Shaul Yarkoni, M.D., Chairman, Department of Obstetrics and Gynecology, (413) 499-4161, ext. 2202.

An equal opportunity employer

Berkshire Medical Center
BERKSHIRE HEALTH SYSTEMS
725 North Street, Pittsfield, MA 01201

Join the Group in Minneapolis.

Outstanding career opportunity combining superior care with professional growth. Join progressive department of 20 physicians, 12 nurse-midwives and 6 ob/gyn nurse practitioners delivering 300 babies each month and providing family planning, infertility, high-risk obstetrics, laser surgery, colposcopy, ultrasonography, laparoscopy and maternal/fetal medicine in one of America's leading metropolitan areas.

Comprehensive benefits including professional liability, four weeks vacation, two weeks conference leave, sick leave, medical coverage, dental coverage, life insurance, disability and retirement plans. Opportunities for teaching and university affiliation. Please send c.v. to: **M. Aksoy, M.D., Chairman, Department of Obstetrics and Gynecology; GROUP HEALTH, INC.; 2829 University Ave. S.E., Suite 220; Minneapolis, MN 55414.**

CHIEF of OBSTETRICS

Specialist in MATERNAL-FETAL MEDICINE

Immediate opening at HARVARD COMMUNITY HEALTH PLAN for senior Obstetrician to supervise the Brigham & Women's Hospital HCHP delivery service. Will serve on hospital's executive committee.

STAFF Obstetricians — several positions for our staff and group model HMO practices. Serving over 300,000 New England residents, we offer excellent benefits and salary commensurate with experience. Board Certified or Eligible candidates please contact Marc Bard, M.D., HCHP, One Fenway Plaza, Boston, MA 02215, 617-731-8275

Harvard Community Health Plan

Maternal-Fetal Medicine

Board certified/eligible PERINATOLOGISTS required for large volume obstetric services (3,000-6,000 deliveries per year).

Opportunities exist both to join and create high risk obstetric services at various Kaiser Permanente Medical Care Centers located in Southern California. University affiliations and clinical research is encouraged.

Excellent benefits are offered including liability coverage, medical and dental coverage, vacation and sick leave, continuing education and retirement program. Partnership consideration available after two years full time employment.

Please write, including your curriculum vitae and three professional references to:

OBSTETRICIAN GYNECOLOGIST-IN-CHIEF

The Mary Imogene Bassett Hospital, a 189-bed, rural referral center, and major teaching affiliate of Columbia University, is seeking candidates for this key appointment. The chief is responsible for overall clinical and teaching programs in Obstetrics and Gynecology. The Service is providing approximately 500 deliveries and about 4300 obstetrical clinic visits yearly. Volume in Gynecology is about 290 admissions and 7800 clinic visits. The department has four attending physicians, rotating transitional residents, a certified nurse midwife, a physician's assistant, plus substantial nursing and office staffing.

Cooperstown, on scenic Lake Otsego about 60 miles west of Albany, enjoys unusual recreational opportunities, a strong school system, and an array of cultural and artistic activities. The village is known for its air of history, museums and resort facilities.

The medical staff is organized as a salaried group practice with full fringe benefits including malpractice coverage, generous free time, conference leave, and immediate annuity participation.

Please send curriculum vitae and correspondence to:

Harlan D. Alpern, M.D.
Search Committee Chairman
The Mary Imogene Bassett Hospital
Cooperstown, New York 13326

REPRODUCTIVE ENDOCRINOLOGY RESEARCH FELLOWSHIP

This research fellowship, beginning July 1987, is designed for gynecologists who are already board-eligible in the Reproductive Endocrinology and Infertility Subspecialty by the American Board of Obstetrics/Gynecology. This 2-3 year research fellowship will equip the candidate with specific training in the laboratory aspects of clinical and basic research in Reproductive Endocrinology. It is specifically aimed at those choosing academic careers who feel the need for further research training upon completion of their clinical training. For information, please write to George S. Richardson, M.D., Acting Chief, Dpt. of Gynecology, Vincent 1, Massachusetts General Hospital, Boston, MA 02114.

PACIFIC NORTHWEST

Practice opportunity available in Arlington, Washington in Obstetrics/Gynecology

New 48-bed hospital (to replace existing facility) under construction, will open summer 1987; office space available adjacent to hospital. Service area is approximately 45,000. Cascade Valley Hospital is affiliated with Virginia Mason Medical Center in Seattle.

Candidates must be board certified or intending to become certified within one year. Must also desire to live in the Arlington area.

Arlington is a rural community of 3,000 located 45 minutes north of Seattle at the foothills of the Cascades and 20 minutes from Puget Sound. The area offers excellent schools and outdoor recreational opportunities.

Please send CV to Patty House, Health Resource Services, 925 Seneca Street, Box 1930, Seattle, WA 98111. (206) 223-6351.

MRHP **Michael Reese Health Plan**

A LARGE HOSPITAL-BASED HMO

has openings for the following full-time position:

Obstetrician Gynecologist

THE MICHAEL REESE HEALTH PLAN, a well-established and rapidly-expanding, federally-qualified HMO seeks Board Certified/Eligible Obstetrician/Gynecologists.

THIS POSITION entails both outpatient and hospital practice as well as medical students and house staff teaching.

REMUNERATION is high and competitive with academic and fee-for-service practice markets. Fringe benefits are generous.

INTERESTED APPLICANTS should send Curriculum Vitae in confidence to:
Dr. Stephen Contro, Medical Director, MICHAEL REESE HEALTH PLAN, 2545 Martin Luther King Drive, Chicago 60616

an equal opportunity employer m/f/h

FACULTY POSITIONS MATERNAL FETAL-MEDICINE

The Department of Obstetrics and Gynecology at the Medical College of Ohio at Toledo, is accepting applications for full time faculty positions within the Division of Maternal Fetal Medicine. The Center for Women and Children is the level III Perinatal Referral Center for Northwest Ohio and has over 4400 deliveries yearly. There is a 60 bed NICU with 6 full time neonatologists. The candidate should be board certified or board eligible in Maternal Fetal Medicine. Duties will include patient care, teaching activities with residents and medical students and development of research activities. Salary and academic rank will be commensurate with the candidate's training and experience. Please direct inquiries and curriculum vitae to:

Roger R. Lenke, M.D.
Associate Professor
Director Maternal Fetal Medicine
Medical College of Ohio
C.S. 10008
Toledo, Ohio 43699
419-381-4591

PERINATOLOGIST
Denver, Colorado

Rose Medical Center, Denver, Colorado, is seeking a BE/BC perinatologist to work full-time in a 400-bed private community hospital adjacent to the University of Colorado Health Sciences Center. With 3600 deliveries per year, and thirty-six University residents rotating through the department annually, Rose is the major private teaching affiliate of the University.

Responsibilities would include private consultation, physician, resident, and nursing education, clinical research, and a limited private practice in perinatology. This individual can expect frequent interaction with the Maternal/Fetal Medicine division at the University of Colorado and would be eligible for an appropriate clinical appointment at the University.

A competitive salary guarantee is being offered with excellent fringe benefits including malpractice insurance.

Qualified applicants, including individuals completing fellowship in June, 1987 should forward CV's to:
Robert E. Wall, M.D.
Chairman, Department of OB/GYN
Rose Medical Center
4567 E. Ninth Avenue
Denver, Colorado 80220

Subspecialist Positions

615-bed tertiary care facility is seeking several board eligible or board certified subspecialists for the following areas within an expanding Department of Obstetrics and Gynecology.

- **Maternal/Fetal Medicine**
  Two new positions available in our established division of Maternal/Fetal Medicine. Ultrasound experience desirable.
- **Reproductive Endocrinology**
  An exceptional growth opportunity is available for a physician to direct this new division.

These positions offer excellent opportunities for professional development to qualified physicians interested in subspecialty practice, resident training, and research/faculty status in a large university affiliated hospital.

SINAI HOSPITAL OF DETROIT

Please submit your Curriculum Vitae or contact **Dr. David B. Schwartz, Chairman, Department of Obstetrics and Gynecology, Sinai Hospital of Detroit, 6767 W. Outer Drive, Detroit, MI 48235, or call (313) 493-5220.**

OBSTETRICIAN GYNECOLOGIST

Position available with The Permanente Medical Group, Inc., San Jose, California. Sixteen member OB/GYN Department seeking Board Certified/Eligible physicians for immediate openings. Excellent professional environment, competitive salary, outstanding benefits. Located in the San Francisco Bay Area, with superb educational, cultural and recreational activities.

Contact:

Jerome L. Nehemiah, M.D., Chief
Department of OB/GYN
The Permanente Medical Group, Inc.

San Jose, CA 95119

Faculty Positions Available

University of Wisconsin, Milwaukee Clinical Campus, is seeking two full-time board eligible or board certified physicians for July, 1987.

PERINATOLOGIST: Position includes patient care and teaching with opportunities for basic or clinical research.

REPRODUCTIVE ENDOCRINOLOGIST: Position involves patient care and teaching with opportunities for research. Administrative role includes direction of *in vitro* fertilization program.

Send curriculum vitae to: Phillip R. Hamilton, M.D., Chairman, Department of Obstetrics and Gynecology, Mount Sinai Medical Center, 950 North 12th Street, Milwaukee, Wisconsin 53233.

GYNECOLOGIC ONCOLOGIST

The Division of Gynecologic-Oncology, Department of Obstetrics-Gynecology of the New York Hospital-Cornell University Medical Center is seeking a Board Eligible or Board Certified gynecologic-oncologist for a full time faculty position.

Interested persons please send CV to:

Thomas A. Caputo, M.D.
Director Gynecologic Oncology
Department of Obstetrics-Gynecology
The New York Hospital-
Cornell University Medical Center
525 East 68th Street
New York, New York 10021

An equal opportunity employer.

FACULTY POSITION AVAILABLE

The Department of Obstetrics and Gynecology at the Medical College of Ohio is accepting applications for a full-time position as director of the residency training program and generalist in the field of Obstetrics and Gynecology.

The residency director is responsible for administration of the program and patient care, including a busy clinical service along with resident and student teaching. Salary and academic rank will be commensurate with candidate's training and experience. Please direct inquiries and curricula vitae to:

John L. Duhring, M.D.
Chairman and Professor

ANNOUNCING THE
FIRST INTERNATIONAL SYMPOSIUM ON INTRAPARTUM BIOCHEMICAL MONITORING OF THE FETUS
JUNE 1-3, 1987
AT CAESAR'S CASINO AND HOTEL, ATLANTIC CITY, N.J.

This course will provide an update on intrapartum monitoring of fetus by biochemical means. The faculty includes world renowned authorities in the field. The course is designed to permit open question and answer sessions daily. It would also permit participants to address their particular problem to faculty person and other attendees during the Workshop and Free Communication Sessions. Special social program has been arranged for significant others accompanying the participants.

Physicians Fees:
$350
Resident Physicians:
$150
Medical Students, Nurses and Technicians:
$100
Deadline on Free Communication, March 28, 1987.
For further information contact:
Molly Chatterjee, M.D.
Our Lady of Mercy Medical Center
600 East 233rd Street
Bronx, New York 10466
Tel. (212) 920-9647

POSTGRADUATE FELLOWSHIP

MATERNAL-FETAL MEDICINE

Applications are invited for a two-year Fellowship in Maternal-Fetal Medicine under the direction of the Section of Maternal-Fetal Medicine, Department of Obstetrics, Gynecology and Reproductive Sciences, University of Manitoba, Dr. F.A. Manning, Professor. This position is available July 1, 1987.

The successful applicant will receive a comprehensive training experience in all aspects of high-risk obstetrics. Specific instruction in the real-time ultrasound assessment of the fetus using the biophysical profile score, intrauterine transfusion, fetal surgery, and experimental fetal research are an integral part of the program.

Applicants to this fully-funded program should possess Royal College of Physicians and Surgeons certification in Obstetrics and Gynecology or its equivalent. Applications including full C.V. and three professional references should be sent to:

C.R. Harman, M.D., Director
Fellowship Program
Section of Maternal-Fetal Medicine

ORTHO-NOVUM 1/77

TRADEMARK

(norethindrone/ethinyl estradiol)

Tablets

Unique, week-by-week design

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE--This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables, and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

DOSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES: Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing .05 mg or less of estrogen.

CONTRAINDICATIONS: Oral contraceptives should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Oral contraceptive tablets may cause fetal harm when administered to a pregnant woman. Oral contraceptive tablets are contraindicated in women who are pregnant. If the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus (see WARNINGS, No. 5). 8. Benign or malignant liver tumor which developed during the use of oral contraceptives or other estrogen-containing products.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary embolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **CEREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in nonusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers. A prospective study conducted in Great Britain estimated that former users have a risk for all cerebrovascular disease 2.6 times greater than that of nonusers. This risk remained elevated for at least six years after last oral contraceptive use. A prospective study conducted in the United States found that past use of oral contraceptives was associated with increased risk of subarachnoid hemorrhage, the relative risk being 5.3. There was also some evidence from this study that the degree of risk may be related to duration of oral contraceptive use. **MYOCARDIAL INFARCTION:** An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive users was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 100,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor in determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified, it is quite likely that the same synergistic action exists, but perhaps to a lesser extent. A study suggests that some increased risk of myocardial infarction in oral contraceptive users persists following discontinuation of oral contraceptives and that the degree of the residual risk is related to the duration of the past use. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an independent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34 -- 5/100,000; ages 35-44 -- 33/100,000; ages 45-49 -- 140/100,000); the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory disease mortality may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over especially those with other risk factors. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS. There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual partial or complete loss of vision, onset of proptosis or diplopia, papilledema, or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. 4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral contraceptive formulations with high hormonal potency were associated with a higher risk than lower potency formulations and use of oral contraceptives with high hormonal potency and age over 30 years may further increase the woman's risk of hepatocellular adenoma. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY, BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones--both estrogenic and progestational agents--during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General.** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **INFORMATION FOR THE PATIENT: (See Patient Package Insert).**

DRUG INTERACTIONS: Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin, griseofulvin, and tetracycline. **CARCINOGENESIS, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea, usually the most common adverse reaction. Vomiting, occurs in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

OJ-781

ORTHO

#1 for new start patien

What to look for in a phasic†...Reason 2

Low breakthrough bleeding

Only 0.3% discontinuance rate due to breakthrough bleeding

- ☐ High rates of patient acceptance
- ☐ Endometrial support throughout the cycle

7 7 7

Designed for performance

21- and 28-day regimens

ORTHO-NOVUM 7/7/7 Tablets

TRADEMARK

(norethindrone/ethinyl estradiol)

†Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.

Please see complete Prescribing Information, a summary of which appears on the preceding page.

UNIQUE

Full-cycle endometrial support, with no late-cycle progestin increase.

The unique TRI-NORINYL phasing achieves BTB control equivalent to a 1/35 formulation, but with 29% less progestin per cycle. This is, in fact, the greatest progestin reduction of any norethindrone-based multiphasic. TRI-NORINYL lowers progestin where requirements for endometrial support are reduced—with no greater reported BTB than a 1/35 formulation.*

SUPPLIED IN THE EXCLUSIVE SYNTEX WALLETTE™ PILL DISPENSER

Preferred by patients 3 to 1 over other available packages for convenience, discreetness and compliance.**

THE NATURE OF TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

*1/35 formulations contain 1.0 mg norethindrone with 0.035 mg ethinyl estradiol. Data available from Syntex Laboratories, Inc.

**Based on a nationwide, independently conducted survey of prospective oral contraceptive patients. Data available from Syntex Laboratories, Inc.

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see brief summary of full prescribing information on next page.

THE NATURE OF TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)

TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg; 7 inert tablets)

ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications Prevention of pregnancy. *DOSE-RELATED RISK OF THROMBOEMBOLISM.* Because studies have shown a positive association between OC estrogen dose and risk of thromboembolism, it is prudent to minimize estrogen exposure. Prescribe an OC with the least amount of estrogen compatible with an acceptable pregnancy rate and patient acceptance. Start new users on OCs containing 0.05 mg or less of estrogen.

Contraindications 1. Known or suspected pregnancy (see Warning #5). 2. Thrombophlebitis or thromboembolic disorders. 3. Past history of deep vein thrombophlebitis or thromboembolic disorders. 4. Undiagnosed abnormal genital bleeding. 5. OCs should not be used by women who have or have had any of the following: a. cerebral vascular or coronary artery disease, including myocardial infarction. b. known or suspected carcinoma of the breast. c. known or suspected estrogen dependent neoplasia. d. benign or malignant liver tumor that developed during use of OCs or other estrogen containing products.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from OC use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use OCs should be strongly advised not to smoke.

The use of OCs is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing OCs should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with OC use is established. One study demonstrated an increased relative risk for fatal venous thromboembolism and several studies demonstrated it for non-fatal venous thromboembolism. They estimate that OC users are 4-11 times more likely than nonusers to develop these diseases without evident cause. One British study reported an excess death rate of 40% in OC users, most of which resulted from cardiovascular disease. Another British study showed a lower death rate in OC users than controls; an increase in cardiovascular deaths was seen but was not statistically significant. A U.S. prospective study failed to disclose increased mortality rates from cardiovascular disorders, but a subset analyzed as a retrospective, case-control study showed significant increases in venous thromboembolism. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke not shown in prior British studies. In an American study of cerebrovascular disorders in women with and without predisposing causes, relative risk of hemorrhagic stroke was estimated as 2.0 times greater and thrombotic stroke as 4-9.5 times greater in users than nonusers. A British long-term follow-up study reported in 1976 a highly significant association between OC use and stroke. Another study had suggested an association in 1974, but the number of cases was too small to estimate the risk. Subarachnoid hemorrhage has been shown to be increased by OC use in British and American studies. Smoking alone increases incidence of these accidents; smoking and pill use appear to increase risk more than either alone.

MYOCARDIAL INFARCTION (MI). Increased relative risk of MI associated with OC use has been reported. One British study found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of OC use. OCs were an additional risk factor. In terms of relative risk, it has been estimated that nonsmoking OC users (smoking is considered a major predisposing condition to MI) are twice as likely to have a fatal MI as nonsmoking nonusers. OC users who are smokers have a 5-fold increased risk of fatal infarction compared to nonsmoking users, and a 10-12-fold increased risk compared to nonsmoking nonusers. The number of cigarettes smoked is important. In determining the importance of these relative risks, baseline rates for various age groups must be considered. (Estimates are based on British vital statistics which show acute MI death rates 2-3 times less than in the U.S. so U.S. death rates could be higher.) Importance of other predisposing conditions in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. Using data from several national adverse reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to estrogen dose in OCs. OCs with 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg but quantity of estrogen may not be the sole factor. This was supported by a U.S. study. A British study found a positive association between dose of progestogen or estrogen and certain thromboembolic conditions. Swedish authorities noted decreased reporting of thromboembolic episodes when higher estrogen preparations were no longer prescribed. Careful epidemiological studies to determine degree of thromboembolic disease risk associated with progestogen-only OCs have not been done. Thromboembolic disease has been reported in women using these products, and they should not be considered free of excess risk. PERSISTENCE OF RISK. Two studies have suggested an increased risk may persist for 6 years after discontinuation of OC use for cerebrovascular disease and 9 years for MI; another study suggested the persistence of risk for subarachnoid hemorrhage. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES. A large British prospective study estimated mortality rate per 100,000 women per year from circulatory system diseases for OC users and nonusers according to age, smoking habits, and duration of use. The overall annual excess death rate for OC users was estimated to be 20/100,000 (ages 15-34 – 5/100,000; ages 35-44 – 33/100,000; ages 45-49 – 140/100,000). Risk is concentrated in long-term users and in smokers, and may persist after OC discontinuation. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all occurred in women 35 or older. An update provided the following rates: ages 15-34 – 1/6700 for nonsmokers and 1/2000 for smokers; ages 45 and over – 1/2500 for nonsmokers and 1/500 for smokers. Risk appeared to increase with parity, but not with duration of use. Until more women under 35 with continuous use for 5 or more years are available, it is not possible to assess relative risk for this age group. Data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. Estimates include combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease for OCs) plus risk attributable to pregnancy or abortion if the method fails (which varies with the effectiveness of the contraceptive method). The study concluded that mortality associated with all contraceptive methods is below that of childbirth, except for OCs in women over 40 who smoke. (Rates given for pill only/smokers for each age are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates would be about double; for "light" smokers (less than 15), about half.) The lowest mortality is with the condom or diaphragm backed up by early abortion. The study also concluded that OC users who smoke, especially over 30, have greater mortality risk than OC users who do not smoke.

Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and for MI is further increased by hypertension, hyperlipidemias, obesity, diabetes, or history of preeclamptic toxemia, and especially by smoking. The following chart gives a gross estimate of risk of death from circulatory disorders associated with OC use.

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS – RISK ASSOCIATED WITH USE OF OCs

Age	Below 30	30-39	40 +
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (no predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A

A – Use associated with very high risk.
B – Use associated with high risk.
C – Use associated with moderate risk.
D – Use associated with low risk.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, discontinue OC immediately. A 4-6 fold increased risk of post-surgery thromboembolic complications has been reported in OC users. If feasible, discontinue OCs at least 4 weeks before surgery associated with increased risk of thromboembolism or prolonged immobilization. Before resuming OC after major surgery or bedrest, balance risks of post-surgery thromboembolic complications with contraceptive needs. Data suggest varicose veins substantially increase risk of superficial venous thrombosis of the leg, the risk depending on the severity of the varicosities. 2. *Ocular Lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OC use. Discontinue OC if there is unexplained, sudden, or gradual, partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions, and institute appropriate diagnostic and therapeutic measures. 3. *Carcinoma:* Long-term continuous administration of natural or synthetic estrogen in certain animals increases certain tumors, benign or malignant, such as breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently in OCs, increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies reported an increased relative risk (31-13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women. One publication reported the first 30 cases submitted to the registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding when OCs were first given, polycystic ovaries), nearly all occurred in women who had used sequential OCs, which are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs, although individual cases have been reported. Studies have shown no increased risk of breast cancer to OC or estrogen users. One study found no overall increased risk of breast cancer in OC users but a greater risk was suggested for OC users with documented benign breast disease and for long-term (2-4 years) users. Another study found a history of breast cancer among grandmothers or aunts was significantly more frequent among breast cancer patients who had used an OC continuously for one or more years than among nonusers with breast cancer. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. One author suggests that extended (over 6 years) OC use prior to first full term pregnancy was associated with a significant relative risk of breast cancer, and other studies suggested an increased risk of breast cancer with long-term OC use before age 25. A reduced occurrence of benign breast tumors in OC users has been well documented. One study reported malignant melanoma more frequently in OC users than controls and suggests an increased incidence of urinary tract and thyroid cancers. A prospective study of women with cervical dysplasia found an increase in severity and conversion to cancer *in situ* in OC users compared to nonusers. This became statistically significant after 3-4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to predict progression after prolonged exposure. One study disclosed an increased risk of cancer of the cervix (largely carcinoma *in situ*) in OC users under 40, particularly those who had used OCs over 4 years. Two other studies suggested an increasing incidence of cervical neoplasms with longer duration of OC use. There have been other reports of microglandular hyperplasia of the cervix in OC users. One study reported an association between OC use and endocervical adenocarcinoma. In summary, there is no confirmed evidence from human studies of increased risk of cancer associated with OCs. Close clinical surveillance of all OC users is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, take appropriate diagnostic measures to rule out malignancy. Monitor OC users with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms with particular care. 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with short-term and long-term OC use. One study reported use of OCs with high hormonal potency and age over 30 may further increase risk of hepatocellular adenoma. Two studies relate risk with duration of use, risk being much greater after 4 or more years of use. Long-term OC users have an estimated annual incidence of hepatocellular adenoma of 3-4/100,000. Although an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may show a focal defect. Hepatic arteriography may be useful in diagnosing primary liver neoplasm. 5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring:* Use of female sex hormones – estrogenic and progestational agents – during early pregnancy may seriously damage the offspring. Females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1/1000 exposures or less. Although there is no evidence that OCs further enhance the risk of developing this type of malignancy, such OC users should be monitored with particular care. A high percentage of women exposed to diethylstilbestrol (30-90%) have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are a precursor of vaginal malignancy. Male children so exposed may develop urogenital tract abnormalities. Although similar data are not available on other estrogens, it cannot be presumed that they would not induce similar changes. Increased risk of congenital anomalies, including heart and limb defects, has been reported following use of sex hormones, including OCs, in pregnancy. One case-control study estimated a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some exposures involved only a few days of treatment. Data suggest risk of limb-reduction defects in exposed fetuses is somewhat less than 1/1000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8/1000 for children not so exposed *in utero*. These results are statistically significant. A Welsh study found a statistically significant excess of neural tube defects among offspring of prior OC users (within 3 months) than among controls. The incidence of twin births may be increased for women who conceive shortly after discontinuing OC use. In the past, female sex hormones were used during pregnancy in an attempt to treat threatened or habitual abortion. There is evidence that estrogens are ineffective, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. If the patient has not adhered to the prescribed schedule, consider possible pregnancy at the first missed period (or 45 days from the last menstrual period if progestogen-only OCs are used) and discontinue OC use until pregnancy has been ruled out. For any patient who has missed two consecutive periods, rule out pregnancy before continuing the OC. If pregnancy is confirmed, tell the patient about potential risks to the fetus and discuss advisability of continuing the pregnancy. Women who discontinue OCs to become pregnant should use an alternate form of contraception for a period of time before attempting to conceive. A 3-month period is supported by a study suggesting increased frequency of neural tube defects in women impregnated during the first 3 months after cessation of OC use. Do not use progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding as a pregnancy test. 6. *Gall Bladder Disease:* Studies report increased risk of gall bladder disease in OC or estrogen users. In one study, an increased risk appeared after 2 years of use and doubled after 4-5 years. In another study, an increased risk was apparent between 6 and 12 months. 7. *Carbohydrate and Lipid Metabolic Effects:* Because a decrease in glucose tolerance has been observed in a significant percentage of patients on OCs, prediabetic and diabetic OC users should be carefully observed. An increase in triglycerides and total phospholipids has been observed in OC users but its clinical significance is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with OC use. Hypertension may occur within a few months of beginning OCs. In the first year of use, incidence of hypertension may be no higher in OC users than in nonusers. Incidence in users increases with exposure and in the fifth year of use is 2.5-3 times that in the first year. Age is strongly correlated with hypertension in OC users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, history of toxemia or elevated blood pressure during pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevated blood pressure when given OCs and should be monitored closely. Even though elevated blood pressure may remain within the "normal" range, closely watch elevations, particularly for women with other risk factors for cardiovascular disease or stroke. High blood pressure may or may not persist after OC discontinuation. 9. *Headache:* Discontinue OC and evaluate the cause of onset or exacerbation of migraine or development of a new pattern of headache which is recurrent, persistent, or severe. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed menses often make users discontinue OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, consider nonfunctional causes. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, use adequate diagnostic measures to rule out pregnancy or malignancy. If pathology has been excluded, time or another formulation may solve the problem. While potentially useful in minimizing menstrual irregularity, change to an OC with a higher estrogen content only if necessary since this may increase the risk of thromboembolic disease. Women with a history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may tend to remain anovulatory or to become amenorrheic after OC discontinuation. Women with these preexisting problems should be advised of this and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with amenorrhea in former users compared with nonusers. One study reported a 16-fold increased incidence of pituitary prolactin-secreting tumors among patients with postpill amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing OCs in comparison with other contraceptive methods, which appears to be independent of duration of use. While impairment diminishes with time, there is an appreciable difference in the results in nulliparous women for OC and other groups 30 months after discontinuation of birth control. For parous women the difference is not apparent 30 months after cessation of contraception. One study suggests *Chlamydia trachomatis* infection, the leading cause of nongonococcal P.I.D., is enhanced by OCs. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in OC failure. In progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in nonusers, since the drugs are more effective in preventing intrauterine than ectopic pregnancies. 13. *Breast Feeding:* OCs in the postpartum period may interfere with lactation by decreasing quantity and quality of breast milk. A small fraction of OC hormonal agents has been identified in milk of mothers receiving OCs. Effects, if any, on the breast-fed child have not been determined. If feasible, defer OC use until the infant has been weaned. **Precautions** *GENERAL* 1. Take a complete medical and family history before starting OCs. Pretreatment and periodic physical exams should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant lab tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may enlarge. 3. Observe patients with a history of psychic depression and discontinue OCs if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the OC and use an alternate method of contraception to determine whether the symptom is drug related. 4. OCs may cause some fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions that might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while using OCs. Discontinue OC if jaundice develops. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism that may result in a relative pyridoxine deficiency. The clinical significance is unknown. 8. Serum folate levels may be depressed by OC use. Since the pregnant woman is predisposed to folate deficiency and incidence of folate deficiency increases with increasing gestation, if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and related complications. 9. Advise the pathologist of OC use when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing OCs. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. f. Increased phospholipids and triglycerides. g. Temporarily decreased glucose tolerance. 11. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist and temporary or permanent cessation of wear considered. DRUG INTERACTIONS. OCs may be less effective and there may be increased breakthrough bleeding from interactions with rifampin, isoniazid, ampicillin, tetracycline, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers, antimigraine preparations, antihistamines, and griseofulvin. OCs may alter effectiveness of such other drugs as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., guanethidine), vitamins, hypoglycemic agents, tranquilizers, hypnotic preparations, theophylline, and beta blockers. Toxic liver effects have been reported with a combination of an OC and cyclosporin A. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings. **Adverse Reactions** An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, Raynaud's disease, arterial thromboembolism. The following adverse reactions have been reported in OC users and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment), gastrointestinal symptoms (nausea, vomiting, bloating, abdominal cramps, colitis), dysmenorrhea, infertility after discontinuance of treatment, edema, chloasma or melasma which may persist after drug is discontinued; breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, changes in corneal curvature (steepening), change in weight (increase or decrease), change in cervical erosion and cervical secretion, possible diminution of lactation when given immediately postpartum, cholestatic jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors, chilblains. The following adverse reactions have been reported in OC users and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, vaginitis, porphyria, impaired renal function, malignant nephrosclerosis (hemolytic uremic syndrome), malignant hypertension, acute renal failure. **Information for the Patient** (See Patient Package Insert).

A Standard in Progesterone Therapy

Provera® 10 MG TABLETS
(medroxyprogesterone acetate)

WARNING

THE USE OF PROGESTATIONAL AGENTS DURING THE FIRST FOUR MONTHS OF PREGNANCY IS NOT RECOMMENDED.

Progestational agents have been used beginning with the first trimester of pregnancy in an attempt to prevent habitual abortion or treat threatened abortion. There is no adequate evidence that such use is effective and there is evidence of potential harm to the fetus when such drugs are given during the first four months of pregnancy. Furthermore, in the vast majority of women, the cause of abortion is a defective ovum, which progestational agents could not be expected to influence. In addition, the use of progestational agents, with their uterine-relaxant properties, in patients with fertilized defective ova may cause a delay in spontaneous abortion. Therefore, the use of such drugs during the first four months of pregnancy is not recommended.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies including congenital heart defects and limb reduction defects. One study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000.

If the patient is exposed to PROVERA Tablets (medroxyprogesterone acetate) during the first four months of pregnancy or if she becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus.

INDICATIONS: Secondary amenorrhea; abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology such as fibroids or uterine cancer.

CONTRAINDICATIONS: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or patients with a past history of these conditions. Liver dysfunction or disease. Known or suspected malignancy of breast or genital organs. Undiagnosed vaginal bleeding. Missed abortion. Known sensitivity to medroxyprogesterone acetate. As a diagnostic test to pregnancy.

WARNINGS: 1. Immediately discontinue administration should any of the following thrombotic disorders occur or be suspected: thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis. **2.** Beagle dogs treated with medroxyprogesterone acetate developed mammary nodules some of which were malignant. Although nodules occasionally appeared in control animals, they were intermittent in nature; whereas the nodules in the drug treated animals were larger, more numerous, persistent, and there were some breast malignancies with metastases. Their significance with respect to humans has not been established. **3.** Discontinue medication pending examination if there is sudden partial or complete loss of vision, onset of proptosis, diplopia, or migraine. If papilledema or retinal vascular lesions occur, withdraw medication. **4.** Detectable amounts of progestin have been identified in the milk of mothers receiving the drug. The effect of this on the nursing infant has not been determined. **5.** Usage in pregnancy is not recommended (see Warning box). **6.** Three major studies in Great Britain and one in this country have shown a statistically significant association between thrombophlebitis, pulmonary embolism, cerebral thrombosis and embolism and the use of oral contraceptives. It has been estimated that users are several times as likely to undergo thromboembolic disease without evident cause as nonusers. The American study indicated that the risk did not persist after discontinuation, and it was not enhanced by long-continued administration.

PRECAUTIONS: A pretreatment physical exam should include special reference to breast and pelvic organs and a Papanicolaou smear. This drug may cause fluid retention; therefore, carefully observe patients with conditions influenced by fluid retention such as epilepsy, migraine, asthma, and cardiac or renal dysfunction. In irregular bleeding per vaginum, bear in mind nonfunctional causes and perform adequate diagnostic measures. Advise pathologist of therapy when submitting relevant specimens. Carefully observe patients with history of psychic depression and discontinue drug if serious depression recurs. Any possible influence of prolonged therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study. Decreased glucose tolerance has been observed in a small percentage of patients on estrogen-progestin combinations; therefore, carefully observe diabetic patients receiving progestin therapy. Age constitutes no absolute limiting factor, although onset of climacteric may be masked. Because of the occasional occurrence of thrombotic disorders (thrombophlebitis, pulmonary embolism, retinal thrombosis, and cerebrovascular disorders) in patients taking estrogen-progestin combinations and since the mechanism is obscure, the physician should be alert to the earliest manifestation of these disorders. (See Patient Information for complete prescribing information.)

ADVERSE REACTIONS: Pregnancy: (see Warning box); **Breast:** rare reports of breast tenderness or galactorrhea; **Skin:** sensitivity reactions including pruritus, urticaria, edema and generalized rash; acne, alopecia and hirsutism in a few patients; **Thromboembolic Phenomena** including thrombophlebitis and pulmonary embolism.

The following adverse reactions have been observed in women taking progestins including medroxyprogesterone acetate: breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; edema; change in weight; changes in cervical erosion and secretions; cholestatic jaundice; rash (allergic) with and without pruritus; mental depression; anaphylaxis and anaphylactoid reactions; pyrexia; insomnia; nausea and somnolence.

A statistically significant association has been demonstrated between use of estrogen-progestin combination drugs and the serious adverse reactions of thrombophlebitis, pulmonary embolism and cerebral thrombosis and embolism. Therefore, patients on progestin therapy should be carefully observed.

Although available evidence is suggestive, a relationship has been neither confirmed nor refuted for the association of the serious adverse reaction of neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been observed in patients receiving estrogen-progestin combination drugs: rise in blood pressure in susceptible individuals; premenstrual-like syndrome; changes in libido; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; fatigue; backache; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; and itching.Therefore, observe patients on progestin therapy carefully.

The following laboratory results may be altered by the use of estrogen-progestin combination drugs: increased sulfobromophthalein retention and other hepatic function tests; coagulation tests (increase in prothrombin factors VII, VIII, IX and X); metyrapone test; pregnanediol determination; thyroid function tests (increase in PBI, and butanol extractable protein bound iodine and decrease in T^3 uptake values).

Caution: Federal law prohibits dispensing without prescription.

Miles Pharmaceuticals

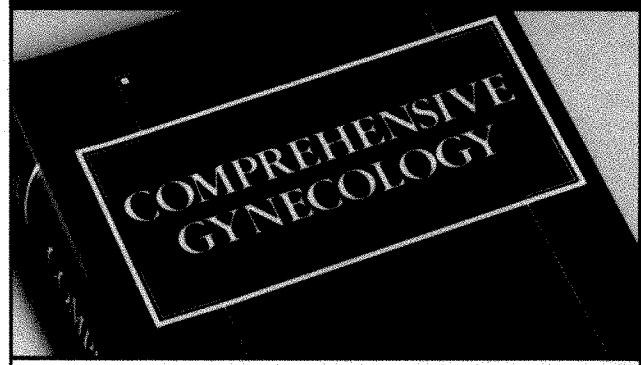
Mycelex® Twin Pack
(clotrimazole)

One-day therapy
Mycelex®-G 500mg
(clotrimazole) Vaginal Tablet

Seven-day therapy
Mycelex® 1%
(clotrimazole)
Cream



Indications
MYCELEX®-G 500 mg Vaginal Tablets are indicated for the local treatment of vulvovaginal candidiasis when one-day therapy is felt warranted. In the case of severe vulvovaginitis due to candidiasis, longer antimycotic therapy is recommended.
MYCELEX® CREAM is indicated for the topical treatment of dermal infections due to *Candida albicans*.
Contraindications
MYCELEX-G 500 mg Vaginal Tablets and MYCELEX CREAM are contraindicated in women who have shown hypersensitivity to any of their components.
Warnings
MYCELEX-G 500 mg Vaginal Tablets: none. MYCELEX CREAM is not for ophthalmic use.
Precautions
MYCELEX-G 500 mg Vaginal Tablets: If there is a lack of response to the Vaginal Tablets, appropriate microbiological studies should be repeated to confirm the diagnosis and rule out other pathogens before instituting another course of antimycotic therapy.
MYCELEX CREAM: If irritation or sensitivity develops with the use of Mycelex Cream, treatment should be discontinued and appropriate therapy instituted.
Carcinogenesis
MYCELEX-G 500 mg Vaginal Tablets: No long-term studies in animals have been performed to evaluate the carcinogenic potential of 500 mg Vaginal Tablets intravaginally. A long-term study in rats (Wistar strains) where clotrimazole was administered orally provided no indication of carcinogenicity.
Usage in Pregnancy: Pregnancy Category B:
MYCELEX-G 500 mg Vaginal Tablets: The disposition of ^{14}C-clotrimazole has been studied in humans and animals. Clotrimazole is poorly absorbed following intravaginal administration to humans, whereas it is rather well absorbed after oral administration.
In clinical trials, use of vaginally applied clotrimazole in pregnant women in their second and third trimesters has not been associated with ill effects. There are, however, no adequate and well-controlled studies in pregnant women during the first trimester of pregnancy. Because animal reproduction studies are not always predictive of human response, this drug should be used only if clearly indicated during the first trimester of pregnancy.
MYCELEX CREAM: In the first trimester of pregnancy, Mycelex Cream should be used only when considered essential to the welfare of the patient.
Adverse Reactions
MYCELEX-G 500 mg Vaginal Tablets: Of 297 patients in double-blind studies with the 500 mg vaginal tablet, 3 of 149 patients treated with active drug and 3 of 148 patients treated with placebo reported complaints during therapy that were possibly drug related. In the active drug group, vomiting occurred in one patient, vaginal soreness with coitus in another, and complaints of vaginal irritation, itching, burning and dyspareunia in the third patient. In the placebo group, clitoral irritation occurred in one patient and dysuria, described as remotely related to drug, in the other. A third patient in the placebo group developed bacterial vaginitis which the investigator classed as possibly related to drug.
MYCELEX CREAM: The following reactions have been reported in connection with the use of this cream: erythema, stinging, blistering, peeling, edema, pruritus, urticaria, and general irritation of the skin.

Innovation Plus Expertise!

COMPREHENSIVE GYNECOLOGY

By William Droegemueller, M.D.; Arthur L. Herbst, M.D.; Daniel R. Mishell, Jr., M.D.; and Morton A. Stenchever, M.D.

Innovative enough to emphasize the psychosocial treatment of your patient, with the expertise to cover a full range of diseases and physical problems — this combination brings you the first, all new comprehensive gynecology text in years! Comprehensive discussions on:

- the most current treatments available
- psychosocial approaches to the troubled patient
- family planning and pregnancy termination
- breast disease and sexually transmitted diseases, including AIDS in women
- rape, incest and other physical abuse

The Key Terms and Definitions that begin each chapter and the synopsis of Key Points at the end provide a quick review. Sophisticated graphics highlight pertinent data. Written by four well-known specialists who share their experience and expertise, COMPREHENSIVE GYNECOLOGY presents state-of-the-art information you'll refer to again and again.

July, 1987. Approx. 1,000 pages with 800 illustrations. (Book Code: 01929) About $60.00 (U.S.); $82.95 (Can.)

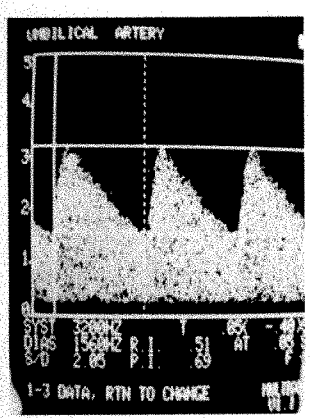
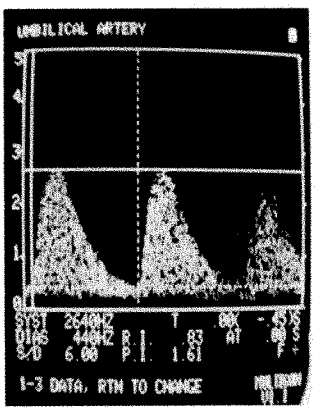
500A™ UMBILICAL-UTERINE ARTERY DOPPLER SPECTRUM ANALYZER

LETS YOU EVALUATE

UTEROPLACENTAL PERFUSION BY SPECTRUM ANALYSIS OF UMBILICAL AND MATERNAL UTERINE ARTERY DOPPLER WAVEFORMS



CLINICAL RESULTS[1-8] SHOW THAT YOU CAN:



- DETECT *IUGR* FROM 20 WEEKS IN SINGLETON PREGNANCIES AND 30 WEEKS IN TWIN PREGNANCIES
- USE UTERINE ARTERY WAVEFORMS IN THE MANAGEMENT OF MATERNAL PREECLAMPSIA
- USE UMBILICAL ARTERY VELOCITY WAVEFORMS IN THE MANAGEMENT OF DIABETIC PREGNANCIES

Umbilical and uterine artery waveforms are easily obtained from early pregnancy on. Low power continuous wave Doppler spectrum analysis is used in a simple test to measure the peripheral resistance in the placental circulation. This resistance is measured by taking the ratio of the systolic to diastolic (S/D) velocity. The S/D ratio is compared to established normal values to determine the presence of abnormal resistance.

The Model 500A™ automatically computes the systolic to diastolic ratio as well as resistance and pulsatility indices.

Normal Umbilical Waveform
S/D = 2.05

Abnormal Umbilical Waveform
S/D = 6.00

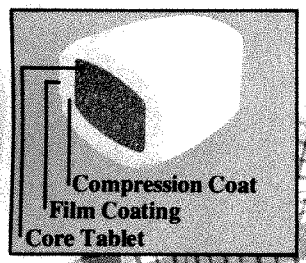
Natalins® Rx

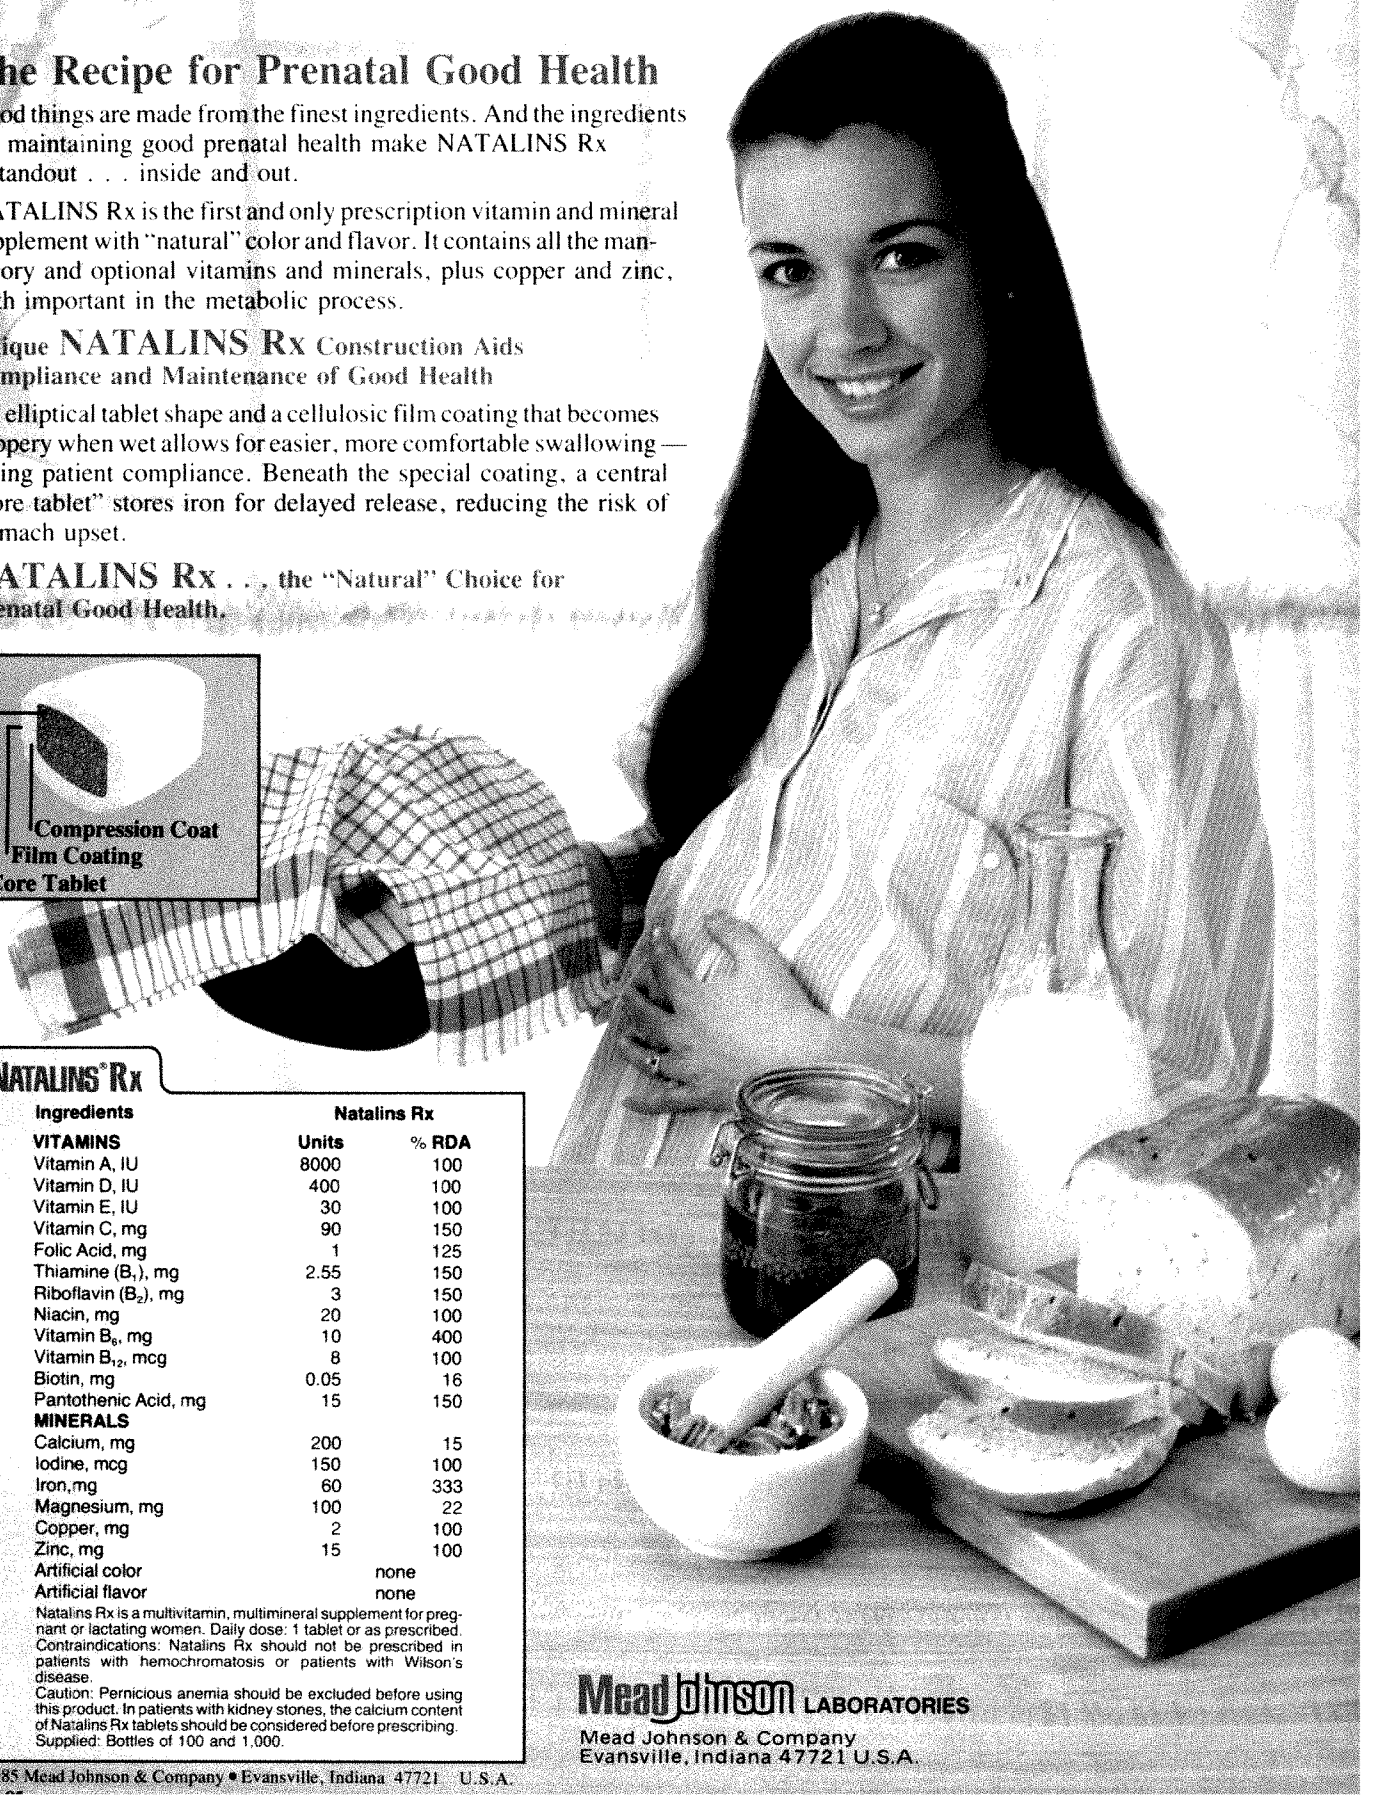
Multivitamin and Multimineral Supplement with 1 mg Folic Acid

The Only Prenatal Vitamin with No Artificial Color or Flavor from Synthetic Sources

The Recipe for Prenatal Good Health



Good things are made from the finest ingredients. And the ingredients for maintaining good prenatal health make NATALINS Rx a standout . . . inside and out.



NATALINS Rx is the first and only prescription vitamin and mineral supplement with "natural" color and flavor. It contains all the mandatory and optional vitamins and minerals, plus copper and zinc, both important in the metabolic process.

Unique NATALINS Rx Construction Aids Compliance and Maintenance of Good Health

An elliptical tablet shape and a cellulosic film coating that becomes slippery when wet allows for easier, more comfortable swallowing — aiding patient compliance. Beneath the special coating, a central "core tablet" stores iron for delayed release, reducing the risk of stomach upset.

NATALINS Rx . . . the "Natural" Choice for Prenatal Good Health.

NATALINS® Rx

Ingredients	Natalins Rx	
VITAMINS	**Units**	**% RDA**
Vitamin A, IU	8000	100
Vitamin D, IU	400	100
Vitamin E, IU	30	100

Iron, mg	60	333
Magnesium, mg	100	22
Copper, mg	2	100
Zinc, mg	15	100
Artificial color		none
Artificial flavor		none

Natalins Rx is a multivitamin, multimineral supplement for pregnant or lactating women. Daily dose: 1 tablet or as prescribed.
Contraindications: Natalins Rx should not be prescribed in patients with hemochromatosis or patients with Wilson's disease.
Caution: Pernicious anemia should be excluded before using this product. In patients with kidney stones, the calcium content of Natalins Rx tablets should be considered before prescribing.
Supplied: Bottles of 100 and 1,000.

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULAR.)*

PREMARIN® Brand of conjugated estrogens tablets, USP

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent, case-controlled studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than one year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case-controlled studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semi-annual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing, in later life, a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1,000 exposures. Furthermore, a high percentage of such exposed women (from 30% to 90%) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb-reduction defects. One case-controlled study estimated a 4.7-fold increased risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than 1 per 1,000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. If PREMARIN is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the advisability of pregnancy continuation.

DESCRIPTION: PREMARIN (conjugated estrogens tablets, USP) for oral administration contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens.

INDICATIONS AND USAGE: Moderate to severe *vasomotor* symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression without associated vasomotor symptoms and they should not be used to treat such conditions.) Osteoporosis (abnormally low bone mass). Atrophic vaginitis. Kraurosis vulvae. Female castration.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

Concomitant Progestin Use: The lowest effective dose appropriate for the specific indication should be utilized. Studies of the addition of a progestin for 7 or more days of a cycle of estrogen administration have reported a lowered incidence of endometrial hyperplasia. Morphological and biochemical studies of the endometrium suggest that 10 to 13 days of progestin are needed to provide maximal maturation of the endometrium and to eliminate any hyperplastic changes. Whether this will provide protection from endometrial carcinoma has not been clearly established. There are possible additional risks which may be associated with the inclusion of progestin in estrogen replacement regimens. (See PRECAUTIONS.) The choice of progestin and dosage may be important; product labeling should be reviewed to minimize possible adverse effects.

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy (see Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

WARNINGS: Estrogens have been reported to increase the risk of endometrial carcinoma (see Boxed Warning). However, a recent large, case-controlled study indicated no increase in risk of breast cancer in postmenopausal women. A recent study has reported a 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease in women receiving postmenopausal estrogens.

Adverse effects of oral contraceptives may be expected at the larger doses of estrogen used to treat prostatic or breast cancer or postpartum breast engorgement; it has been shown that there is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement. Users of oral contraceptives have an increased risk of diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis, thromboembolic disorders, or in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast have been shown to increase the risk of nonfatal myocardial infarction, pulmonary embolism and thrombophlebitis. When doses of this size are used, any of the thromboembolic and thrombotic adverse effects should be considered a clear risk.

Benign hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has been reported in women taking estrogen-containing oral contraceptives. Increased blood pressure may occur with use of estrogens in the menopause and blood pressure should be monitored with estrogen use. A worsening of glucose tolerance has been observed in patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc. Prolonged administration of unopposed estrogen therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Oral contraceptives appear to be associated with an increased incidence of mental depression. Patients with a history of depression should be carefully observed. Pre-existing uterine leiomyomata may increase in size during estrogen use. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, metabolic bone diseases associated with hypercalcemia, or in young patients in whom bone growth is not yet complete. If concomitant progestin therapy is used, potential risks may include adverse effects on carbohydrate and lipid metabolism.

The following changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T_4 by column, or T_4 by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered.

d. Impaired glucose tolerance.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. However, in a recent, large case-controlled study of postmenopausal women there was no increase in risk of breast cancer with use of conjugated estrogens.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy, including oral contraceptives: breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis, change in cervical erosion and in degree of cervical secretion; cystitis-like syndrome; tenderness, enlargement, secretion (of breasts); nausea, vomiting, abdominal cramps, bloating; cholestatic jaundice; chloasma or melasma which may persist when drug is discontinued; erythema multiforme; erythema nodosum; hemorrhagic eruption; loss of scalp hair; hirsutism; steepening of corneal curvature; intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea, and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION: 1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause (0.3 mg to 1.25 mg or more daily).

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (eg, three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

2. *Given cyclically:* Osteoporosis. Female castration.

Osteoporosis —0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off).

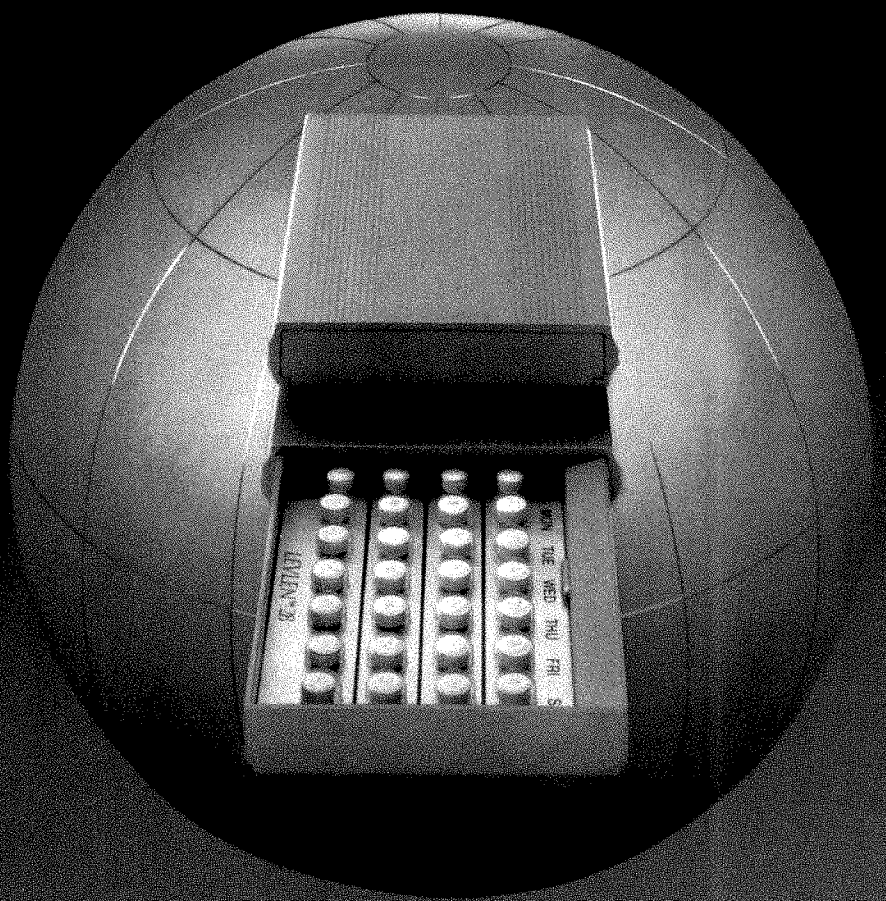
Female castration—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Patients with an intact uterus should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

PREMARIN®

(Conjugated Estrogens Tablets)

Complete estrogen therapy



Ayerst® AYERST LABORATORIES
New York, NY 10017

6339/1286

LEVLEN™

(Levonorgestrel 0.15 mg and ethinyl estradiol 0.03 mg tablets)

THE MOST WIDELY PRESCRIBED OC FORMULA IN THE WORLD

The dose is low

There is no lower total hormonal dose in a monophasic OC.

Available in 28-day and 21-day Slidecase™ dispensers

The confidence is high

Incidence of breakthrough bleeding at cycle 6 is a low 5.6% based on 17 studies.[1]

Minimal impact on blood pressure[1] and lipids[2] in certain specific studies.*

*Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptom of serious disease and discontinue oral contraceptive therapy when appropriate. These data represent only the results of selected studies, therefore, before prescribing, the physician should read and remain alert to all data found in the complete prescribing information for the product. Please also see brief summary of prescribing information on next page of advertisement.

LEVLEN™28 LEVLEN™21

BERLEX™ Dedicated to innovation in OB/GYN medicine

LEVLEN™ 28
LEVLEN™ 21

(Levonorgestrel 0.15 mg and ethinyl estradiol 0.03 mg tablets)

BRIEF SUMMARY

Each Levlen tablet contains 0.15 mg of levonorgestrel (d (-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.03 mg of ethinyl estradiol (19-nor-17 α-pregna-1,3,5 (10)-trien-20-yne-3,17-diol) (7 pink inert tablets are included in Levlen 28).

Indications and Usage—Levlen is indicated for the prevention of pregnancy in women who elect to use OCs as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions. 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only OCs have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. (The rates given for Pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to six-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs instead of other methods of contraception. Furthermore, a high percentage of such exposed women (. . .in 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only OCs are used), and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. However, in progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in women who are not receiving OCs, since the drugs are more effective in preventing intrauterine than ectopic pregnancies.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination being performed.

2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency.

Information for the Patient—See patient package labeling.

Laboratory Tests—1. The pathologist should be advised of OC therapy when relevant specimens are submitted.

2. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs:

a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thryoid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis, Mutagenesis, Impairment of Fertility—See "Warnings" section #3, 4 and 5 for information on carcinogenesis, mutagenesis and impairment of fertility.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings." Because of the potential for adverse reactions in nursing infants from OC tablets, a decision should be made whether to discontinue the drug, taking into account the importance of the drug to the mother.

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis; pulmonary embolism; coronary thrombosis; cerebral thrombosis; cerebral hemorrhage; hypertension; gallbladder disease; benign hepatomas; congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally; gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted: premenstrual-like syndrome; cataracts; changes in libido; chorea; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; vaginitis; porphyria; hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Levlen must be taken exactly as directed and at intervals not exceeding 24 hours.

Any time the patient misses 1 or 2 light-orange tablets, she should also use another method of contraception until she has taken a light-orange tablet daily for 7 consecutive days.

For full details on dosage and administration, see prescribing information in package insert.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the *American Journal of Obstetrics and Gynecology* conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1982;96(6):766-71. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from The C. V. Mosby Company or the Editors on request.

Manuscripts should be submitted to one of the three Editors as follows: (1) Dr. Brewer—all articles originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies; (2) Dr. Zuspan—articles from the northeastern quadrant of the United States, Japan, Israel, Italy, and England, articles written for Clinical Opinion and Current Development, and Letters to the Editors; (3) Dr. Quilligan—articles from the north central states (including Ohio), states west of the Mississippi, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England).

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. **Therefore, all manuscripts must be accompanied by the following written statement, signed by one author:** "The undersigned author transfers all copyright ownership of the manuscript [title of article] to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of material.

When submitting a manuscript, an author should include, if applicable, a full statement about all submissions and prior reports in any medium that might be regarded as prior or duplicate publication of the same or similar work. Copies of such material should be included with the submitted manuscript. Articles previously published in another language will not be considered.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority. Articles dealing with human experimentation that require local institutional approval must have this approval prior to submission of the article for publication and it should be so indicated in the Methods section. Reports of experiments on animals must indicate which guidelines for the care and use of the animals were followed.

Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither Editor(s) nor Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality copies of the manu-

script and three glossy prints of illustrations are required.

Manuscripts must be typed double spaced on one side only on 22 by 28 cm (8 1/2 by 11 inch) white bond paper with 1 inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, abstract, body of text, references, legends, and tables.

Title page. The title page should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of all authors and their highest academic degree (both M.D. and Ph.D. are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; acknowledgement of source(s) of support; presented line, if applicable; disclaimers, if any; name and address of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name and address of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Abstract page and key words/phrases. On manuscript page two is the abstract, also typed double spaced with the required margins and headed by the title of the article and author(s) name(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations since the emphasis is on the "action" rather than the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods section* describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results section* present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your observations to those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment section* state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgements. Acknowledge only persons who have made substantive contributions to the study.

References. Limit of 16 references, except for case reports and brief communications, limited to 2, and Current Development, for which there is no limit. Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Illustrations and tables. A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for color reproduction. For color photographs, submit original transparencies and two sets of unmounted prints on glossy paper with good color balance. For black and white illustrations, submit three sets of 3 by 4 inch (minimum) to 5 by 7 inch (maximum) unmounted glossy photographic prints. Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with author(s) name(s), title of article, number, and top marked clearly). Do not use paper clips. Legends must accompany all figures; type double spaced on a single sheet of paper if possible and number with manuscript in sequence after the references. Titles should be included in the legend, *not* on the print.

All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black and white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Illustrations will be returned only on the author's request.

Tables should be typed on separate sheets of paper and included at the end of the text, one to a page. They should be numbered in Roman numerals. Each table must be cited

Estimating length of manuscript

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200 word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7 page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double spaced with the required 1 inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 typed words in manuscript. Thus if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table and each column precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Illustrations and tables should supplement, not duplicate, the text; presentation in either one or the other will suffice.

Permissions and photographic consent. Previously published tables and figures must be correctly referenced and written permission from the copyright holder included with the manuscript. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

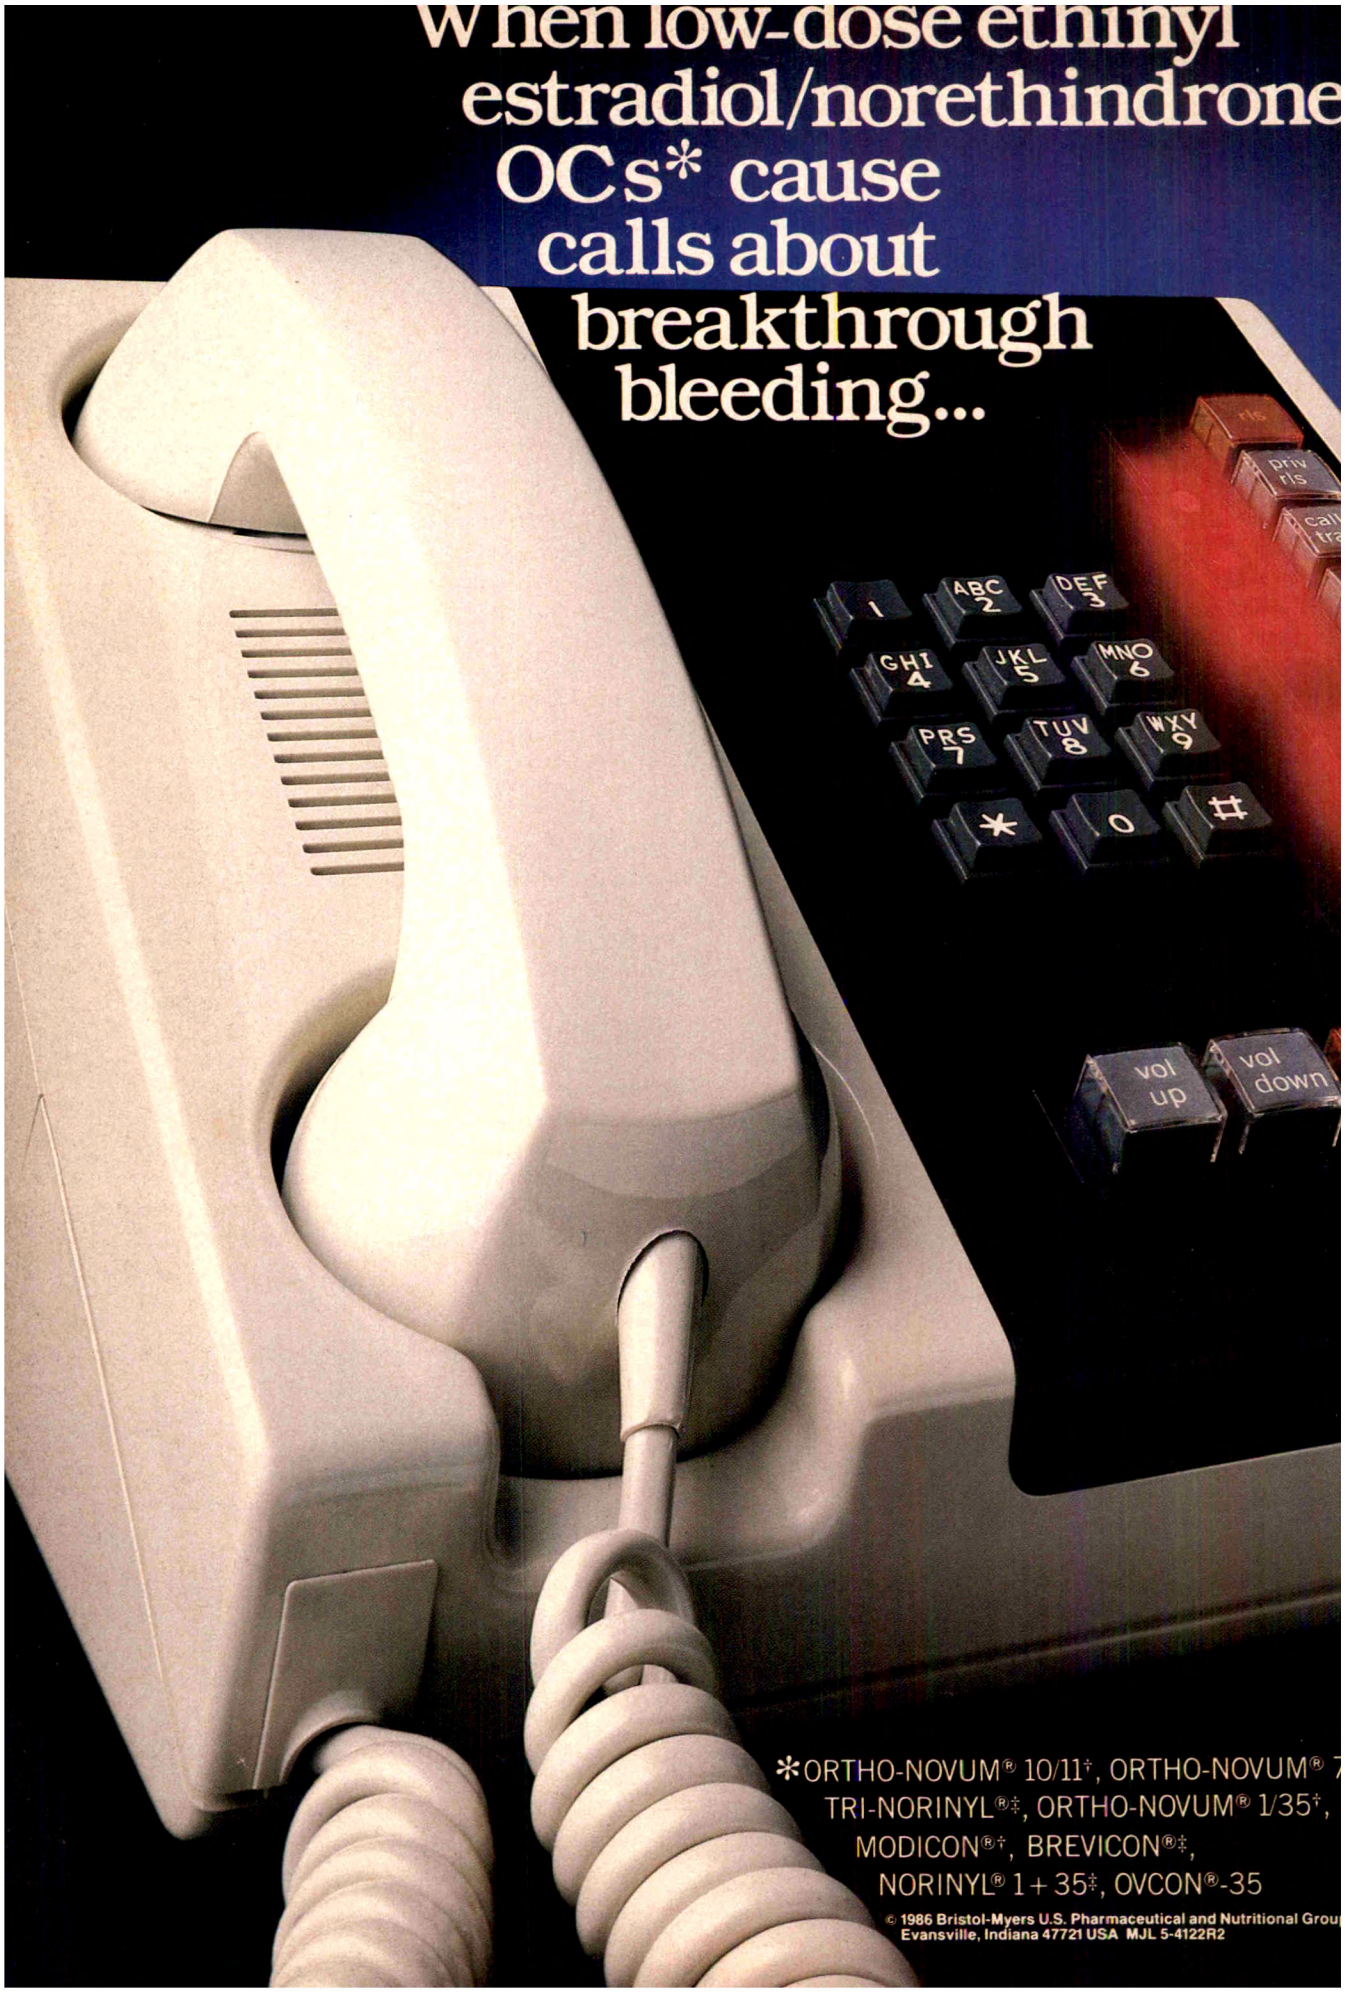
Current Investigation. Same requirements as for a regular article.

Clinical Opinion. Limit of 3000 words, 16 references. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

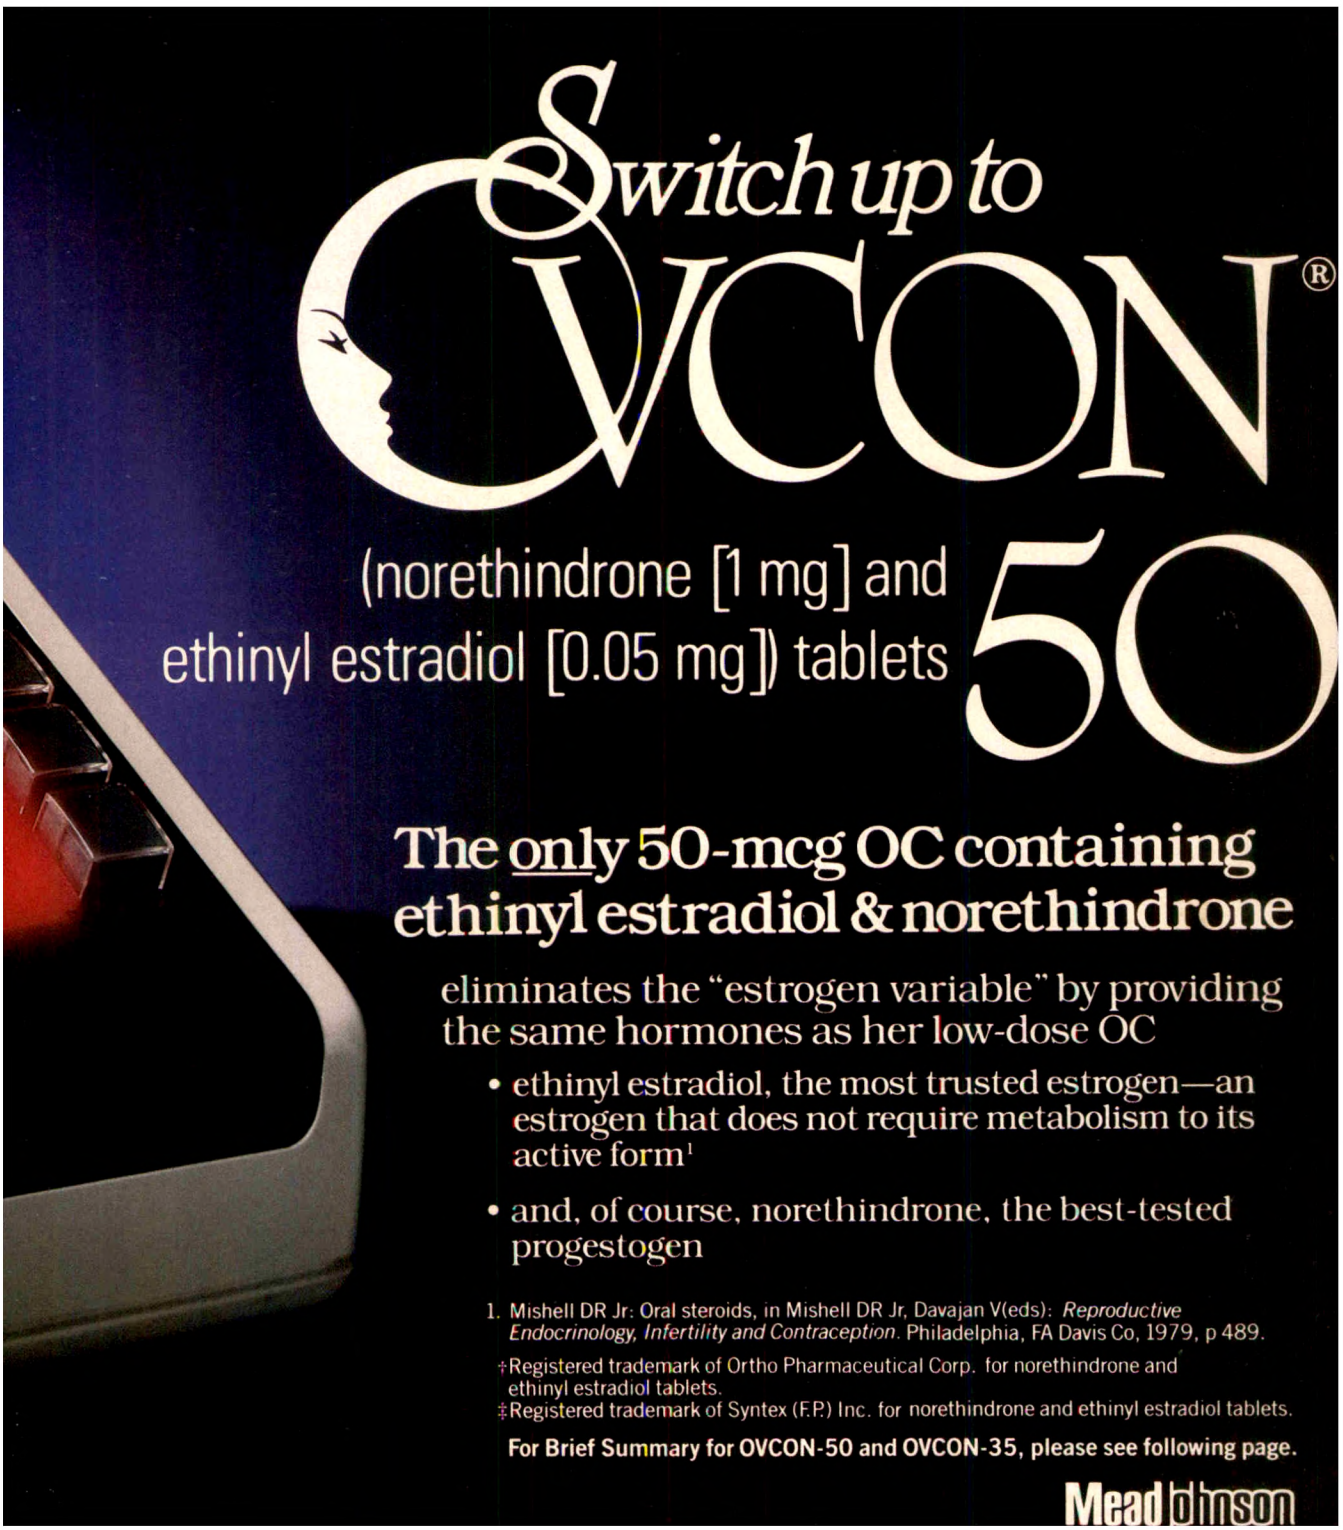
Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication. All letters should be typed double spaced. Letters should be sent to Dr. Zuspan.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60.00 U.S. and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146.



Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.



Reprints. Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications. Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, or call Journal Advertising Production Manager (314) 872-8370.

Checklist

—Letter of submission
—Copyright transfer letter
—Original and two xerographic copies of manuscript
—Title page
—Title of article
—Full name(s) and affiliations of author(s)
—Author to whom correspondence is to be sent
—Reprint request line or line stating reprints not available
—Short title
—Abstract (double spaced), 3 to 5 key words/phrases
—Article proper (double spaced)
—References (double spaced), on a separate sheet
—Legends (double spaced), on a separate sheet
—Tables (double spaced), each on a separate sheet
—Illustrations, properly labeled (three copies of glossy prints)
—Permission to reproduce published material

When low-dose ethinyl estradiol/norethindrone OCs* cause calls about breakthrough bleeding...

(norethindrone [1 mg] and
ethinyl estradiol [0.05 mg]) tablets
50
The only 50-mcg OC containing
ethinyl estradiol & norethindrone
eliminates the "estrogen variable" by providing
the same hormones as her low-dose OC
• ethinyl estradiol, the most trusted estrogen—an estrogen that does not require metabolism to its active form[1]
• and, of course, norethindrone, the best-tested progestogen

Mead Johnson

OVCON®-50

(norethindrone [1 mg] and ethinyl estradiol [0.05 mg]) tablets

OVCON®-35

(norethindrone [0.4 mg] and ethinyl estradiol [0.035 mg]) tablets

Indications and Usage: Ovcon is indicated for the prevention of pregnancy. Some combination products containing 35 mcg. or less of ethinyl estradiol report slightly higher pregnancy rates than are reported for the higher dose combination products.

Dose-related Risk of Thromboembolism from Oral Contraceptives: Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing 50 mcg. or less of estrogen.

Contraindications: Oral contraceptives should not be used in women with any of the following conditions: 1) Thrombophlebitis or thromboembolic disorders. 2) A past history of deep vein thrombophlebitis or thromboembolic disorders. 3) Cerebral vascular or coronary artery disease. 4) Known or suspected carcinoma of the breast. 5) Known or suspected estrogen dependent neoplasia. 6) Undiagnosed abnormal genital bleeding. 7) Known or suspected pregnancy. 8) Benign or malignant liver tumor which developed during the use of oral contraceptives or other estrogen-containing products.

Warnings:

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. Women who use oral contraceptives should be strongly advised not to smoke. Use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1) *Thromboembolic Disorders and Other Vascular Problems.* An increased risk of thromboembolic and thrombotic disease associated with use of oral contraceptives is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. In a study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater. An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported. Studies conducted in the United Kingdom found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction compared to nonusers who do not smoke. Oral contraceptive users who smoke have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. The amount of smoking is a very important factor. British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives; preparations containing 100 mcg. or more of estrogen were associated with a higher risk of thromboembolism than those containing 50–80 mcg. of estrogen. The relative risk of thromboembolic disease associated with progestin-only oral contraceptives has not been determined. Cases of thromboembolic disease have been reported in women using progestin-only products, and they should not be presumed to be risk-free. The overall excess mortality rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15–34, 5/100,000; ages 35–44, 33/100,000; ages 45–49, 140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. The highest risk was found in heavy cigarette smokers (15 or more cigarettes per day) who used oral contraceptives and were aged 40 or older. Women who smoke should be advised not to use oral contraceptives. The use of oral contraceptives in women over age 40 with other risk factors is not recommended. The mortality associated with all of the methods of birth control is low compared to the risk of childbirth, with the exception of oral contraceptive users who smoke and are over age 40. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and for myocardial infarction is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia, and especially by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. If feasible, oral contraceptives should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2) *Ocular Lesions.* There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue the medication if there is unexplained sudden or gradual, partial or complete loss of vision; sudden onset of proptosis or diplopia; papilledema; or retinal vascular lesions, and institute appropriate diagnostic and therapeutic measures. 3) *Carcinoma.* Long term administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. In humans, one study investigated the first 21 cases of endometrial adenocarcinoma in women on oral contraceptives reported to a registry. Of those women without predisposing risk factors for this disease, nearly all occurred in women who had used a sequential oral contraceptive. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestin-only oral contraceptives. No increase in breast cancer in women taking oral contraceptives has been reported although one study reported an increased risk of breast cancer in subgroups of women treated using oral contraceptives with documented benign breast disease. There is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives. 4) *Hepatic Adenoma.* Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study reported a higher risk associated with oral contraceptive formulations with high hormonal potency. Although benign and rare, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short term as well as long term users of oral contraceptives. Two studies relate the risk with duration of contraceptive use, the risk being much greater after 4 or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass, or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5) *Use in Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring.* Fetal abnormalities have been reported to occur in the offspring of women who have taken progestogens and/or estrogens during pregnancy. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. A high percentage of such exposed women (30% to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Similar data are not available with the use of other estrogens but it cannot be presumed that they would not induce similar changes. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000 live births. In the past, female abortion. There is considerable evidence that estrogens are ineffective for these indicatio there is no evidence from well-controlled studies that progestins are effective for these Increases in chromosomal aberrations have been reported in women who become pregnan after ceasing oral contraceptive therapy. Embryos with these anomalies are virtually spontaneously aborted. Whether there is an overall increase in spontaneous abortion of pregn conceived soon after stopping oral contraceptives is unknown. It is recommended that for any who has missed two consecutive periods, pregnancy should be ruled out before continui contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possib pregnancy should be considered at the time of the first missed period and further use contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirm patient should be apprised of the potential risks to the fetus and the advisability of preg continuation should be discussed in light of these risks. It is also recommended that wome discontinue oral contraceptives with the intent of becoming pregnant use an alternate fo contraception for a period of time before attempting to conceive. Many clinicians recommen months. Administration of progestin-only or progestin-estrogen combinations to induce with bleeding should not be used as a test for pregnancy. 6) *Gall Bladder Disease.* Studies have repo increased risk of surgically confirmed gallbladder disease appearing after one year c contraceptive use and doubling of the risk after 4 or 5 years of use. 7) *Carbohydrate and Metabolic Effects.* A decrease in glucose tolerance has been observed in a significant percent patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be ca observed while receiving oral contraceptives. Increased serum levels of triglycerides an phospholipids have been observed in oral contraceptive users. The clinical significance observation is unknown at this time. 8) *Elevated Blood Pressure.* An increase in blood pressu been reported in women receiving oral contraceptives. The prevalence of hypertension contraceptive users may be no higher than nonusers in the first year of oral contraceptive u increases with longer exposure and in the fifth year of use is two and one-half to three tim reported prevalence in the first year. Women who previously had hypertension during pregnanc be more likely to develop elevation of blood pressure when given oral contraceptives. 9) *Head* The onset or exacerbation of migraine or development of headache of a new pattern wh recurrent, persistent or severe, requires discontinuation of oral contraceptives and investiga the cause. 10) *Bleeding Irregularities.* Breakthrough bleeding, spotting and amenorrhea are fre reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all ca irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiag persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measur indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or cha another formulation may solve the problem. Changing to an oral contraceptive with a higher est content, while potentially useful in minimizing menstrual irregularity, should be done necessary since this may increase the risk of thromboembolic disease. Women with a past hist oligomenorrhea or secondary amenorrhea or young women without regular cycles may h tendency to remain anovulatory or to become amenorrheic after discontinuation o contraceptives. Women with these preexisting problems should be advised of this possibili encouraged to use other contraceptive methods. 11) *Ectopic Pregnancy.* Ectopic as w intrauterine pregnancy may occur in contraceptive failures. However, in oral contraceptive fai the ratio of ectopic to intrauterine pregnancies is higher than in women not using oral contrace since the drugs are more effective in preventing intrauterine rather than ectopic pregnanc higher ectopic-intrauterine ratio has been reported with both combination products and prog only oral contraceptives. 12) *Breast Feeding.* A small fraction of the hormonal agents i contraceptives has been identified in the milk of mothers receiving these drugs. The long- effect to the nursing infant cannot be determined at this time.

Precautions: 1) A complete medical and family history should be taken prior to the initiation contraceptives. Examination should include special reference to blood pressure, breasts, abd and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a genera oral contraceptives should not be prescribed for longer than 1 year without another ph examination being performed. 2) Under the influence of estrogen-progestogen prepara preexisting uterine leiomyomata may increase in size. 3) Patients with a history of ps depression should be carefully observed and the drug discontinued if depression recurs to a s degree. 4) Because oral contraceptives may cause some degree of fluid retention, conditions might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, carc renal insufficiency or asthma require careful observation. 5) Patients with a past history of jau during pregnancy have an increased risk of recurrence of jaundice while receiving oral contrac therapy. If jaundice develops in any patient receiving such drugs, the medication shou discontinued. 6) Steroid hormones may be poorly metabolized in patients with impaired function and should be administered with caution in such patients. 7) Oral contraceptive user have disturbances in normal tryptophan metabolism which may result in a relative pyrid deficiency. The clinical significance of this is yet to be determined. 8) Serum folate levels m depressed by oral contraceptive therapy. This may complicate subsequent pregnancy with reg folate deficiency. 9) The pathologist should be advised of oral contraceptive therapy when rel specimens are submitted. 10) Certain endocrine and liver function tests and blood component be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein rete b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; incr norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) le to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), column, or T_4 by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the ele TBG; free T_4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced resp to metyrapone test. 11) The active yellow tablets and the inert green tablets in Ovcon-50 (21 a day regimens) and the inert green tablets in the 28 day regimen of Ovcon-35 contain FD&C Yello 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in c susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sens in the general population is low, it is frequently seen in patients who also have a hypersensitivity.

Information for the Patient: Detailed Patient Labeling has been prepared for use by the patient an been made available for distribution by the pharmacist.

Drug Interactions: Reduced efficacy and increased incidence of breakthrough bleeding have associated with concomitant use of rifampin. A similar association has been suggested barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Adverse Reactions: An increased risk of the following serious adverse reactions has been assoc with the use of oral contraceptives (see **Warnings**): Thrombophlebitis, pulmonary embo coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gall bl disease, congenital anomalies. There is evidence of an association between the following condi and the use of oral contraceptives, although additional confirmatory studies are needed: Mese thrombosis; benign hepatomas; neuro-ocular lesions, e.g., retinal thrombosis and optic neu The following adverse reactions have been reported in patients receiving oral contraceptives an believed to be drug related: Nausea and/or vomiting, usually the most common adverse react occur in approximately 10% or less of patients during the first cycle (other reactions, as a ge rule, are seen much less frequently or only occasionally); gastrointestinal symptoms (su abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuar treatment; edema; chloasma or melasma which may persist; breast changes (tender enlargement, and secretion); change in weight (increase or decrease); change in cervical erosio cervical secretion; possible diminution in lactation when given immediately postpartum; chole jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depres reduced tolerance to carbohydrates; vaginal candidiasis; changes in corneal curvature (steeper intolerance to contact lenses. The following adverse reactions have been reported in users o contraceptives, and the association has been neither confirmed nor refuted: Premenstrua syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndr headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, eryt nodosum, hemorrhagic eruption, vaginitis, porphyria.

Acute Overdosage: Serious ill effects have not been reported following acute ingestion of large c of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal blee may occur in females.

EDITORIAL

Summary of analysis of published articles

September 1, 1985, through August 31, 1986

Each year a retrospective analysis of the articles published in the JOURNAL is presented to the readers and also to the Editorial Board and the Advisory Committee on Policy. Over the past seventeen years we have compiled data on the classification, category, and type of articles accepted and published. A comparison of the data for the last two years is presented in Table I. A comparison of publication time in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY of regular articles (excluding society articles) for 1981-1982 through 1985-1986 is shown graphically in Fig. 1, on page 526. Readers and authors should note the time from acceptance to publication was 3.64 months for the period analyzed in 1986.* The circle graphs on page 526 show the articles and page utilization for 1986 by classification (Fig. 2A) and by category (Fig. 2B).

*Publication time of regular articles from time of acceptance to publication: 1982, 4.72 months; 1983, 4.95 months; 1984, 5.60 months; 1985, 4.90 months; 1986, 3.64 months.

Clinical Opinion

The use and misuse of the fetal biophysical profile

Anthony M. Vintzileos, M.D., Winston A. Campbell, M.D., David J. Nochimson, M.D., and Paul J. Weinbaum, M.D.

Farmington, Connecticut

The value of the fetal biophysical profile in determining fetal well-being has been well documented. The increasing clinical use of the fetal biophysical profile, however, has led to the recognition of frequent errors in the interpretation and application of this modality. These errors may result in unnecessary interventions or adverse perinatal outcome. The most frequent errors in the interpretation and application of the fetal biophysical profile are described; in an attempt to minimize the misuse of the fetal biophysical profile, an alternative protocol of antepartum fetal evaluation is suggested based upon the information obtained from the biophysical monitoring of the fetus. (AM J OBSTET GYNECOL 1987;156:527-33.)

Key words: Fetal biophysical profile, antepartum fetal evaluation

The fetal biophysical profile (nonstress test, fetal movements, fetal breathing movements, fetal tone, amniotic fluid volume, placental grading) has been shown to be more accurate in the identification of the compromised fetus than any other single test during the antepartum period.[1-10] Its predictive value in antepartum fetal surveillance has been very well documented for patients with intact as well as ruptured membranes.[1-10] In high-risk patients with intact membranes it has been shown to be more accurate than the contraction stress test[5] and the nonstress test.[11] The method used for determination of the fetal biophysical profile has been previously reported.[1, 5] Fetal biophysical variables have been assigned an arbitrary score of 2 when normal and 0 when abnormal.[1-3] In our institution the fetal biophysical variables, including placental grading, have been assigned an arbitrary score of 2, 1, or 0 (modified from the biophysical scoring of Manning et al.[1-3]). Regardless of the differences in the scoring criteria, in all reported studies a fetal biophysical profile score of 8 or more has been considered reassuring of fetal well-being and a score of 7 or less nonreassuring.[1-10] In the past, management protocols were suggested based on the biophysical profile scoring.[1-3, 5, 6]

The purpose of this communication is to discuss the physiology and pathophysiology of the fetal biophysical activities so that the clinician understands what the presence or absence of a given biophysical activity means, to describe the most frequent errors in the interpretation and clinical application of the fetal biophysical profile, and to present a simple approach of antepartum determination of fetal well-being using the information obtained from the biophysical monitoring of the fetus.

Physiology and pathophysiology of fetal biophysical activities

Dynamic biophysical activities are not random events but rather are initiated and regulated by complex integrated mechanisms of the fetal central nervous system. The presence of a normal biophysical activity is indirect evidence that a given portion of the central nervous system that controls the activity is intact and functioning and therefore nonhypoxemic. The absence of a given fetal biophysical activity, however, is much more difficult to interpret, since it may reflect either pathologic depression or normal periodicity. The periodicity in the biophysical activities has been shown[12, 13] to be short term (20 to 40 minutes) or long term, similar to circadian (diurnal) rhythms seen in extrauterine life.

Factors that cause fetal central nervous system depression may reduce or abolish fetal biophysical activities. Fetal hypoxemia produces a dramatic decrease of fetal heart rate reactivity and fetal breathing movements and, when severe, will result in reduced or absent fetal movements and fetal tone.[5] Central nervous sys-

tem depressants such as analgesics (morphine, meperidine), sedatives (barbiturates, diazepam), and anesthetics (halothane) reduce or inhibit fetal biophysical activities. In contrast, central nervous system stimulants such as hyperglycemia and catecholamines may result in increased biophysical activities.

The nervous impulses that initiate fetal biophysical activities arise from different anatomic sites within the brain.[5, 7, 14] The sensitivity of these areas to hypoxemia is unknown, but it has been strongly suggested that variations in sensitivity exist.[5, 7, 14] During the fetal neurodevelopment, a higher oxygen level is required for newly developing central nervous system centers and for reflex biophysical activities. The biophysical activities that become active first in fetal development are the last to disappear when asphyxia arrests all biophysical activities.[14] For example, the fetal tone center (cortex-subcortical area) is the earliest to function during intrauterine life (7.5 to 8.5 weeks)[14] and is the last to disappear during asphyxia. The fetal movement center (cortex-nuclei) starts functioning at approximately 9 weeks,[15] and accordingly, it is more sensitive to hypoxia than the fetal tone center. Although isolated fetal breathing movements have been documented as early as 13 to 14 weeks, diaphragmatic contraction and regular fetal breathing do not occur until 20 to 21 weeks,[15] when the fetal breathing movement center (ventral surface of the fourth ventricle) is fully developed and functioning. The fetal heart rate reactivity center (posterior hypothalamus, medulla), which starts operating by the end of the second trimester or early third trimester, is therefore the most sensitive to hypoxia. In the antepartum fetal evaluation the presence or absence of the acute markers of the fetal condition (nonstress test, fetal breathing movements, fetal movements, and fetal tone) will determine the level of fetal compromise at the time of testing.[5] The fetus with suboptimal oxygenation will usually present with nonreactive nonstress testing and absence of fetal breathing at the initial stages of hypoxia; if hypoxia becomes worse, the fetal body movements and fetal tone will be abolished (gradual hypoxia concept). In our reported experience[5, 7] all hypoxic fetuses—as determined by umbilical cord pH measurements—had nonreactive nonstress tests and in no cases was fetal breathing present. These hypoxic fetuses had perinatal death rate of 0 when fetal movements were normal. When the fetal movements were decreased or absent, the perinatal death rate ranged from 20% to 75%. When the fetal tone also was poor, the perinatal mortality was 100%. This correlation between the gradual hypoxia concept and perinatal otucome has been further confirmed by our subsequent experience with a total of 6543 fetal biophysical profiles.

Amniotic fluid volume, unlike the other biophysical variables, is not acutely influenced by alterations in fetal central nervous system function. It is included in the fetal biophysical profile because of the high correlation between decreased amniotic fluid volume and increased incidence of abnormal pregnancy outcome.[3, 5, 16] It is a chronic marker of the fetal condition. The mechanism by which chronic fetal asphyxia results in oligohydramnios is not fully elucidated but may involve hypoxia-induced reflex redistribution of cardiac output with preferential shunting of blood away from the lung and kidney, the two major sources of fluid production in later pregnancy.[17] Fetuses with decreased amniotic fluid volume are at high risk for cord compression and in utero death.[3, 5, 7, 16] In our institution placental grading is also included in the fetal biophysical profile, since cases with grade III placentas have been found to be associated with increased incidence of abnormal fetal heart rate patterns and abruptio placentae during labor.[5, 7] The value of including placental grading is to alert the physician during the intrapartum period in the presence of a grade III placenta.

Misuse of the fetal biophysical profile

The most common errors that clinicians make when they use the fetal biophysical profile as a means of antepartum fetal evaluation are outlined below:

Management decisions based on the score alone. This is the most frequent error among clinicians who use the fetal biophysical profile for fetal surveillance. This error may lead to unnecessary interventions or preventable adverse perinatal outcome. Although it has been repeatedly stated[3, 5, 7] that management should be based not solely on the score but also on the score components, this principle has not been emphasized strongly enough in the literature; the end result is that clinicians tend to base their decisions on the score alone. Based on our experience (6543 fetal biophysical profiles over a 4-year period), the correct interpretation of the information obtained from the fetal biophysical monitoring should primarily rest on the individual biophysical components rather than on the score. This approach of considering the components rather than the overall score is an absolute necessity in order to decrease both false positive and false negative examinations. An example of a false positive examination (if the score is to be used for management) is the fetus with the biophysical profile score of 4 as determined by the presence of reactive nonstress test and normal amount of amniotic fluid. This fetus has a nonreassuring score; however, the presence of reactive nonstress test rules out fetal hypoxia, and the fact that the other biophysical components (fetal breathing movements, fetal movements) are not observed during the real-time scanning is due to normal periodicity. The low biophysical score in this case cannot be the result of fetal compromise because the nonstress test is reactive, and

based on the gradual hypoxia concept,[5, 7, 14] one of the first manifestations of fetal compromise should be nonreactive nonstress testing. In this case the overall low biophysical score should not alarm the physician, and the decision on repeat testing or delivery should be decided on the basis of a normal test result. An example of what may turn out to be a false negative examination (if the score is to be used for management) is the case of the fetus with a biophysical score of 8 or more and oligohydramnios. This fetus may be well oxygenated in the presence of normal acute markers (reactive nonstress test and/or fetal breathing present); however, cord accident is a possibility because of oligohydramnios and a vulnerable cord. If the pregnancy is at or near term this fetus should be delivered[3, 16] regardless of the reassuring score because there is a high incidence of cord accident and in utero death in spite of the evidence of good fetal condition at the time of testing, as evidenced by the presence of the other biophysical components. Although previous investigators have suggested a management protocol based on the score, the presence of oligohydramnios has been considered as an indication for delivery regardless of the overall score. In viable preterm gestations, frequent testing or delivery has been advocated depending on the individual case.[3, 7]

Management based on the biophysical profile results without considering the overall clinical context of each case. Disregarding the overall clinical context of a given case and deciding for management on the biophysical profile results alone has been a common error among physicians who utilize the fetal biophysical profile. Since there is no perfect test which, when normal, guarantees good outcome in 100% of the cases, the plan of management should consider the circumstances of each case. In our opinion, even in the presence of a normal biophysical profile result, delivery is indicated in the presence of a growth-retarded fetus with confirmed pulmonary maturity; regardless of the biophysical profile results, delivery is also indicated in postdate pregnancies with a favorable cervix or in the presence of overriding medical complications (for instance, deteriorating pregnancy-induced hypertension). The clinician should realize that the information obtained from the fetal biophysical monitoring is only a part of the entire clinical picture and should be viewed as such in the decision-making process.

Interval between testing when the previous test result is normal, equivocal, or abnormal. The interval between normal test results has in general been 1 week. As a practical rule this frequency of testing may be appropriate in certain cases. However, there are certain high-risk cases (postdate pregnancies, insulin-dependent diabetes mellitus) that are in need of more frequent testing (twice a week); this has been already recognized and suggested by some investigators.[3] In the series of Manning et al.,[3] which involved 12,620 high-risk patients managed with fetal biophysical profile assessment as the means of antepartuum fetal evaluation, there were eight perinatal deaths of structurally normal fetuses within 7 days after a reassuring biophysical assessment. Seven of these eight fetuses had test-to-death interval between 5 and 7 days, and only one had a test-to-death interval of 3 days. It is reasonable to expect that increased frequency of testing (for instance, twice a week) might have prevented some of these deaths. Based on published data[1-4] as well as our experience,[5-10] the only means to reduce the false negative rate is to further increase the frequency of testing. It is our opinion that the interval between normal tests should be individualized according to the circumstances of each case.

In cases with an equivocal or abnormal previous test result, some investigators have advocated repeat testing within 24 hours.[3] Many clinicians will test in 24 hours. We belive that retesting in 24 hours after an equivocal or abnormal test is unreasonable. A delay of 24 hours in cases of a nonreassuring fetal evaluation test has occasionally resulted in intrauterine death. This is a completely preventable castastrophe with no reasonable excuse, given the fact that the previous test was not indicative of fetal well-being. Delaying 24 hours makes no sense if the fetus is really in jeopardy; on the other hand, if the nonreassuring biophysical monitoring is the result of normal periodicity, then a repeat nonreassuring testing 24 hours later may still be the result of absent fetal activities because of normal periodicity. In our opinion there is no room for uncertainty between tests; a definite judgment about fetal condition should be made before the patient is discharged home. Repeat testing within 24 hours, after an equivocal or abnormal test result, is to be avoided; in such cases we would advocate extended testing immediately following the initial nonreassuring test result in order to differentiate the sleeping from the asphyxiated fetus and to avoid in utero deaths that may occur in the interim.

Procrastination or reluctance to act promptly on the abnormal test result. In certain situations, such as gestations with an unfavorable cervix or preterm gestations, there is a natural reluctance from many clinicians to act and pursue appropriately an abnormal test result. The clinician is frequently hesitant to induce labor in a patient with an unfavorable cervix because of the increased risk of failed induction and therefore cesarean section. However, since the clinician chooses to apply fetal evaluation even in patients with unfavorable cervix, he or she is obliged to pursue the abnormal test result rather than procrastinating because of cervical unripeness. In preterm gestations clinicians justify their

procrastination on the assumption that the biophysical activities of the fetus are not known during early gestational ages; in these preterm gestations, however, the clinician should take advantage of the fact that the sleeping cycles of the fetus are much shorter compared to those at term and therefore the incidence of false positive biophysical profile examinations is extremely low. For instance, a fetus at <30 weeks' gestation who does not exhibit any biophysical activities in a 30-minute observation period under real-time scanning is apparently asphyxiated and not sleeping. As the gestational age advances, the sleeping cycles become longer (40 to 60 minutes), and only then may an abnormal biophysical profile result be due to normal periodicity or fetal compromise. It is our opinion that an abnormal fetal biophysical result in a very preterm gestation should be pursued aggressively because it is rarely false positive. The normal fetal biophysical profile and activities in preterm gestations, as well as throughout gestation, have been recently defined by our group.[8]

Assessment of the ultrasound-monitored biophysical variables without including the nonstress test. Although it has been suggested that the addition of the nonstress test does not improve the discriminative accuracy when all ultrasound-monitored variables are normal,[3] we would not advocate this approach. In our opinion the nonstress test should be an integral part of the fetal biophysical monitoring because not only is it a sensitive indicator of fetal condition, but also, if variable decelerations are present, it may select those fetuses who are candidates for a cord accident. Since spontaneous variable decelerations can escape detection when only real-time scanning is used, it is possible to miss the occasional fetus who is a candidate for a cord accident in spite of the presence of normal amniotic fluid. The variable decelerations in these cases may be the result of a cord abnormality (short cord, true knot, etc.) or abnormal cord position (for example, tight nuchal cord). Since certain fetuses who are candidates for a cord accident will manifest spontaneous variable decelerations in the presence of normal amniotic fluid volume, we still continue to use the nonstress test as an integral part of the fetal biophysical profile assessment.

Inexperience of the operator and faulty technique. One of the most frequent errors occurs in the qualitative assessment of the amniotic fluid volume. By definition, measured pockets of amniotic fluid should be free of umbilical cord. It is imperative therefore for the operator to make sure that he does not include cord loops in his measurements. Inclusion of cord loops in the qualitative amniotic fluid assessment will as a result cause a false sense of security that it is a normal amount of amniotic fluid, whereas it may be decreased and the fetus be in jeopardy. Another area that also needs further clarification is the definition of the "normality" of the observed biophysical activities. For the purpose of antepartum fetal surveillance, fetal breathing is considered to be present only if it is continuous (breath-to-breath intervals of <6 seconds). Isolated breathing movements separated by ≥6 seconds should not be considered to be fetal breathing present. Similarly, fetal body movements are considered to be present only if rolling trunk movements are observed (three or more within 30 minutes). Isolated limb movements should not be considered to be fetal movements present. Regarding the ultrasound technique used for assessment of the fetal biophysical variables, it is reasonable to recommend that the operator use the technique with which he is most familiar. The technique that we use for the most part consists of a transverse abdominal scan with simultaneous visualization of the fetal abdomen, fetal limbs, and amniotic fluid. In this plane we measure the largest amniotic fluid pocket and also are able to simultaneously observe any breathing activity (by observing the expansion of the fetal abdominal wall), fetal body movements (as evidenced by rolling circular motion of the spine), and fetal tone (as evidenced by extension of the extremities and return to the position of flexion); very frequently the placenta is also visualized in this plane.

Proposed protocol of antepartum fetal evaluation based on information obtained from the fetal biophysical assessment

It is clear from the aforementioned discussion that the fetal biophysical profile is designed to assist the clinician to ascertain the following: (1) The fetal condition at the time of testing. This judgment should be based on the presence or absence of the acute markers of the fetal condition, namely, the nonstress test, fetal breathing movements, fetal movements, and fetal tone. (2) The degree of fetal compromise. This judgment is based on the presence or absence of the acute markers of the fetal condition interpreted according to the gradual hypoxia concept. (3) The possibility of chronic fetal stress or compromise. This judgment should be made on the basis of the amniotic fluid volume. (4) The possibility of in utero death because of cord accident. This judgment should be made based on the presence or absence of oligohydramnios and/or variable decelerations during nonstress testing. (5) Increased risk for intrapartum abnormal fetal heart rate patterns and abruptio placentae. This judgment should be based on the presence of a grade III placenta. It should also be emphasized that the fetal biophysical profile is designed to detect the presence of anomalous fetuses,[1-3, 5, 7] and this information may modify further management. The fetal biophysical profile was not designed to predict the presence or absence of other abnormal outcomes such

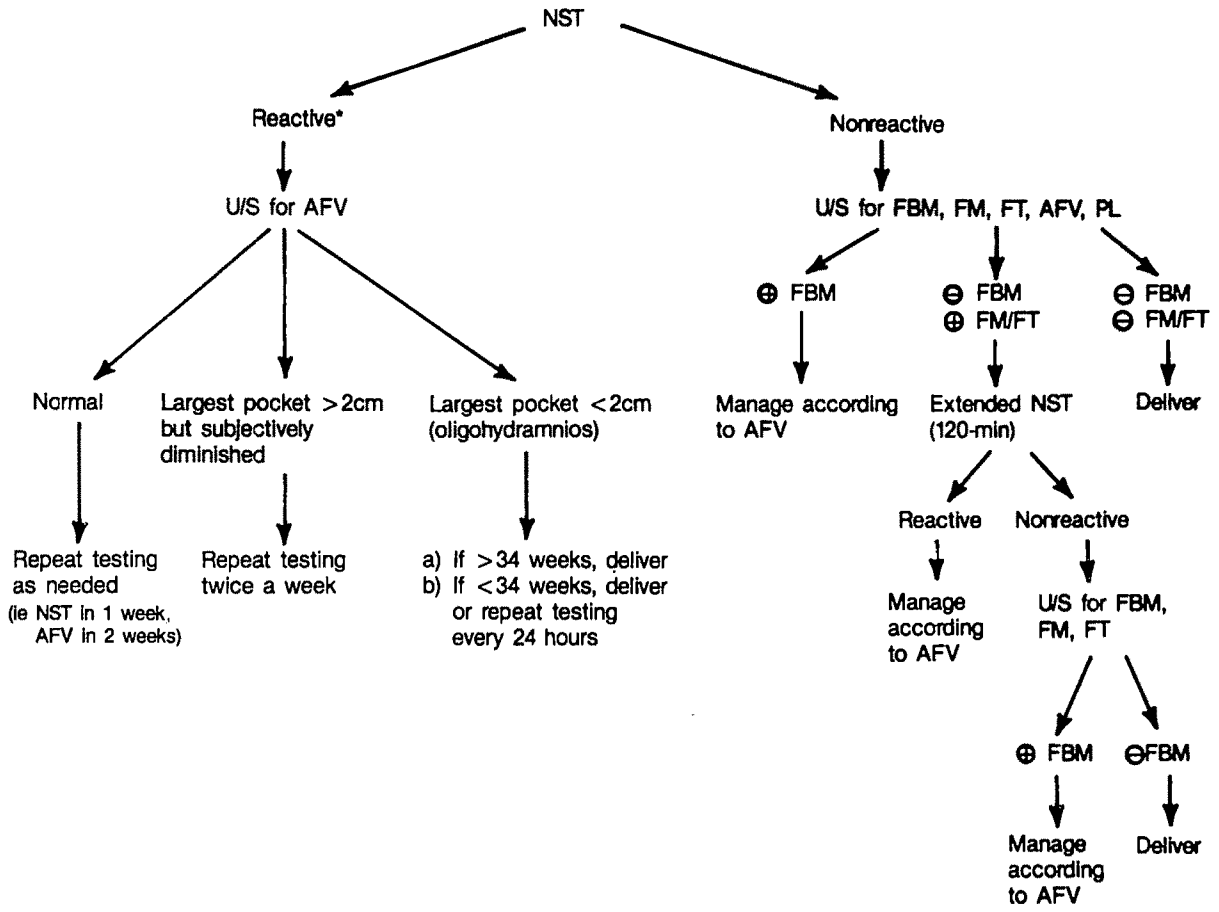

Fig. 1. Protocol of antepartum fetal evaluation for pregnancies with intact membranes. *NST* = Nonstress test, *U/S* = ultrasound, *AFV* = amniotic fluid volume, *FBM* = fetal breathing, *FM* = fetal movements, *FT* = fetal tone, *PL* = placental grading, ⊕ = present/normal, and ⊖ = absent/abnormal. *In the presence of variable decelerations and oligohydramnios consider delivery; in the presence of variable decelerations and normal *AFV* consider extended (120 minutes) or repeat *NST* within 24 hours.

as intrauterine growth retardation, postdatism, ability of the fetus to tolerate labor, meconium aspiration, premature labor, and abruptio placentae.

Considering the physiology and pathophysiology of the fetal biophysical activities as well as the erroneous judgments that could result from using the score alone and not the score components, we recommend an alternative scheme of antepartum fetal evaluation. We have applied this scheme in 6543 fetuses over a 4-year period, and we have encountered only one in utero death, which occurred 2½ weeks after a reassuring fetal biophysical assessment. When evaluating the fetus of a high-risk pregnancy, we ask three questions and the pregnancy is continued only if the fetus qualifies for normality by all three questions:

1. Is the fetus compromised at the time of testing? We recommend that a reactive nonstress test (two or more fetal heart rate accelerations in a 10-minute period) or presence of fetal breathing for >30 seconds[5-7] (even in the presence of a nonreactive nonstress test) indicate fetal well-being at the time of testing. A word of caution should be addressed at this point regarding the presence of fetal breathing as a sign of well-being in fetuses of diabetic mothers. We have encountered two hypoxic fetuses of diabetic mothers who had fetal breathing just before delivery by cesarean section, but in both cases maternal hyperglycemia was present when breathing was observed. Since maternal hyperglycemia increases fetal breathing, we would recommend that fetal breathing should be regarded as a sign of well-being only in the presence of maternal normoglycemia at the time of testing.

In the presence of a nonreactive nonstress test, real-time scanning is performed for a maximum 30-minute observation period. If fetal breathing is detected (lasting >30 seconds, the examination is terminated and further management is based on the amniotic fluid volume assessment. If all acute markers (fetal breathing, fetal movements, fetal tone) are absent or compromised after 30 minutes of continuous observation, prompt

delivery is undertaken. This action is based on the fact that these fetuses almost never improve their biophysical assessment on repeat testing because they are severely compromised.[3, 5] If the fetus has a nonreactive nonstress test and there is absence of fetal breathing but movements and tone are present, we would recommend extended nonstress testing to differentiate sleeping state from asphyxia. The nonstress testing is continued until a reactive pattern is observed or 120 minutes of continuous fetal heart monitoring have elapsed. At the end of the 120-minute period if the nonstress test is still nonreactive, the ultrasound-monitored variables (fetal breathing, fetal movements, and fetal tone) are reassessed. This is helpful in determing the degree of fetal compromise according to the gradual hypoxia concept. If after this extended testing the nonstress test remains nonreactive and no fetal breathing is observed, then delivery is considered. If the fetus is not compromised at the time of testing as evidenced by the presence of a reactive nonstress test and/or fetal breathing, the clinician should proceed with the following question.

2. Is the fetus a candidate for a cord accident? This clinical judgment is based on the presence or absence of oligohydramnios and/or variable decelerations during nonstress testing. If there are no variable decelerations and a normal amount of amniotic fluid, then testing is repeated after individualizing for each case. The presence of oligohydramnios (largest pocket, <2 cm)[5, 16] at a term or near term gestation with intact membranes is considered an indication for delivery regardless of the normality of the other fetal biophysical components because these fetuses are at high risk for cord accident and in utero death. The combination of oligohydramnios and variable decelerations during nonstress testing is an indication for delivery in viable fetuses regardless of gestational age. In a preterm gestation with intact membranes in which fetus seems to be a candidate for a cord accident (as evidenced by decreased amount of amniotic fluid or variable decelerations), individualization is recommended, and if delivery is not undertaken, testing (every 24 hours) is the plan of management. The frequency of testing should be dictated by the amount of amniotic fluid volume. In cases in which the amniotic fluid volume seems subjectively diminished but the largest amniotic fluid pocket measures >2 cm, we would recommend increased frequency of testing (twice a week). If the fetus does not seem to be a candidate for a cord accident, as evidenced by normal amniotic fluid volume and no variable decelerations, then the clinician should proceed with the following question.

3. Is the fetus growing normally? This question mainly pertains to cases of suspected intrauterine growth retardation. In our unit these fetuses are followed by serial ultrasound growth parameters every 2 weeks in addition to the fetal biophysical monitoring. If there is normal rate of growth and normal biophysical assessment, the pregnancy is allowed to continue. However, if there is suboptimal or arrested rate of growth at term or near term, delivery is undertaken. If delayed growth rate is diagnosed in a preterm gestation, frequent biophysical monitoring is indicated.

The protocol of antepartum fetal surveillance for pregnancies with intact membranes, used at the authors' institution, is illustrated in Fig. 1. We believe that this alternative protocol of antepartum fetal surveillance, without including the scoring of the biophysical variables, will eliminate most of the problems encountered in the clinical interpretation and application of fetal biophysical monitoring. The understanding of the physiology, pathophysiology, and the gradual hypoxia concept of the fetal biophysical activities, as well as the significance of oligohydramnios, is imperative for the proper clinical application of this tool and therefore for the improvement of the quality of perinatal care.

Maternal serum α-fetoprotein screening

II. Pitfalls in low-volume decentralized laboratory performance

James N. Macri, Ph.D., Ramana V. Kasturi, B.E., M.S., David A. Krantz, B.S., and Mannshya G. Hu, Ph.D.

Carle Place, New York

Assays of maternal serum α-fetoprotein are subject to the phenomenon of assay drift, which may be defined as incorrect increase or decrease of α-fetoprotein values from their true values. Low maternal serum α-fetoprotein weekly volume (for example, fewer than 500 specimens per week) will result in a >47% probability that 10% assay drift will not be recognized. Further, laboratory reports to clinicians may lead to either misdirecting 43% more pregnant women (with positive drift) into further (possibly invasive) diagnostic procedures or the offer of further diagnostic services to 32% fewer gravidas at increased risk (with negative drift) than should be so managed. We address the problem outlined above and present the reasons for establishment of regional maternal serum α-fetoprotein screening programs operating at sufficient volume to permit the identification and control of assay drift. (AM J OBSTET GYNECOL 1987;156:533-5.)

Key words: Maternal serum α-fetoprotein, assay drift, low volume

Maternal serum α-fetoprotein screening for the prenatal detection of fetal malformations and genetic anomalies is increasingly used in the United States. Because of the structure of health care delivery and the number of clinical laboratories it is possible that this unprecedented, population-based screening process will be provided in a decentralized fashion.

Strong influence to decentralize maternal serum α-fetoprotein screening may be exerted by laboratories situated in hospitals and medical centers. Decentralized, low-volume maternal serum α-fetoprotein screening should be of considerable concern to obstetricians and geneticists. We set forth the reasons for concern and recommend that regional, joint programs be established for safe and effective maternal serum α-fetoprotein screening.

Since it is unlikely that most hospitals or medical centers will care for >3000 obstetric patients per year, small, decentralized maternal serum α-fetoprotein screening programs will be evaluating approximately 12 or fewer patients per day. At such levels of screening, laboratories will be required to use more reagents for standards and controls than for patient specimens. The unfavorable cost effects are obvious. It is inevitable that economic pressure will lead to batching of specimens, increased turnaround time, delayed information flow to physicians and patients, and detriment to the purpose and objectives of maternal serum α-fetoprotein screening.

Few clinical laboratories in the United States have maternal serum α-fetoprotein screening experience. However, many laboratories are permitted to proceed without first having developed their own, independent, normative data and while performing maternal serum α-fetoprotein assays on a low-volume basis.[1] Under such conditions the likelihood of assay imprecision will be great. For example, the report of a workshop sponsored by the National Institute of Child Health and Human Development[2] implies that laboratories evaluating 50 patient specimens per week would require recurring

blocks of time (3 months) and recurring levels of patient volume (600 patients) to be able to assess the quality of assays performed during the 3-month period. These conditions and time lag are incompatible with the best interests of clinicians and patients, who will have already passed critical points of decision-making.

At low-volume levels the intrinsic problems of assay drift could be difficult, if not impossible, to monitor in a timely fashion (before physician receipt of report). The private and public proficiency testing programs that are appearing are not likely to solve for clinicians the inherent potential for inaccuracy which we describe.

Information from proficiency testing programs indicates that even experienced maternal serum α-fetoprotein laboratories will experience assay drift.[3] Unrecognized assay drift will lead to a significant problem manifesting itself in at least two ways: (1) wide differences in the number of patients (among maternal serum α-fetoprotein screening programs) falling into risk categories warranting further evaluation as well as (2) unexplained differences in detection efficiencies between maternal serum α-fetoprotein screening programs. The problem will have negative clinical implications.

Assay drift may be monitored by taking advantage of the central limit theorem, which states that for large volumes of specimens, the mean of the sample is nor-

mally distributed about the population mean. By calculating the mean multiple of the median* for all samples on an individual assay and accepting or rejecting the assay based on whether this mean multiple of the median is within or outside an established range (95% confidence interval), laboratories will be capable of detecting and correcting for assay drift. When an assay is accepted and results are subsequently reported to physicians, there remains the concern that assay drift may have occurred, notwithstanding the fact that the mean multiple of the median for that assay is within the established limits for accepting the individual assay.

Tables IA and IB represent such probabilities based on data established by us from experience in the evaluation of α-fetoprotein from approximately a quarter million pregnancy samples. At an assay volume of 50 specimens the probability of erroneously accepting an assay with a positive 15% drift is in the range of 46%. In this same 50-specimen assay 12.5% drift falls within acceptable limits.

Table II illustrates that, with positive assay drift, more than the accurate number of pregnancies will fall above specified cut-off levels and would unnecessarily receive further, possibly invasive testing. A 5% positive drift would result in 20% of additional pregnant women (53 compared to 44) falling above specified cut-off levels. A 20% positive drift will result in 111% additional pregnant women (93 compared to 44) falling above specified cut-offs. Similarly, negative assay drift will result in erroneously assuring some pregnant women that no further evaluation is necessary.

Unrecognized, positive assay drift resulting in the misdirection of (added numbers) pregnant women to potentially invasive procedures will have a calculable effect on fetal harm. Similarly, unrecognized negative assay drift will result in sharp differences among maternal serum α-fetoprotein screening programs in detection efficiencies for neural tube defects. Highly variable levels of accuracy in maternal serum α-fetoprotein screening will result (and be made available to physicians) from the failure to develop independent normative data and the failure to perform high volume and adequately monitored assays.

*We note that use of multiples of the median as statistical parameters of measurement are appropriate, but they should not be used for reporting to clinicians or patients.

Prevention of preterm birth by ambulatory assessment of uterine activity: A randomized study

John C. Morrison, M.D., James N. Martin, Jr., M.D., Rick W. Martin, M.D., Kathy S. Gookin, R.N., M.S.N., and Winfred L. Wiser, M.D.
Jackson, Mississippi

Tocodynamometry, used on an ambulatory basis, has been shown to detect uterine activity. The objective of this study was to assess the effectiveness of ambulatory tocodynamometry in the early identification of preterm labor. In this investigation 67 women at risk for preterm labor were randomly divided into two groups: 34 received a uterine activity monitor while 33 patients used palpation. Approximately two thirds of the study sample developed preterm labor. Upon diagnosis of preterm labor, parturients in the control group had cervical dilatation of <3 cm ($p < 0.001$) and effacement of >50% more often than the monitored group ($p < 0.01$). As a result there was a significant decrease in the number of patients who responded to tocolytic therapy in the unmonitored group. Among those with preterm labor the time gained in utero was greater in the monitored group (8.2 ± 2.7 weeks) compared to the control group (4.2 ± 2.9 weeks) ($p < 0.05$). Subsequently 29 of 34 monitored patients attained term (36 completed gestational weeks) versus only 18 of the 33 patients in the unmonitored group ($p < 0.01$). Although the sample size is relatively small, uterine activity monitoring in these very high risk patients resulted in an increased number of suitable candidates for tocolysis and allowed a significantly greater percentage of women to reach term. (Am J Obstet Gynecol 1987;156:536-43.)

Key words: Preterm, ambulatory detection, uterine activity

Although there has been tremendous improvement in perinatal morbidity and mortality in the past 20 years, the percent of parturients delivering preterm infants in the United States has remained largely unchanged.[1] In addition, approximately 75% of neonatal mortality is related to respiratory problems that are causally associated with prematurity. Methods of preventing preterm birth have been impaired because the exact etiology of preterm labor has not been delineated.[2] Tocolytic agents are effective in delaying preterm births in selected cases, but in many patients therapy is not salutary because labor is not detected before advanced dilatation of the cervix.[3] Recently, Herron et al.[4] have developed a method of addressing preterm birth that involves identification of high-risk patients as well as educational intervention toward prevention of early delivery. This schema purports to allow earlier identification of labor and thus more timely medical treatment. Unfortunately, many times uterine activity is not perceived by the patient.[5] Also, other studies using the technique of intensive risk assessment and patient education in a socioeconomically disadvantaged population did not find this technique successful in preventing preterm birth.[6]

Bell[7] has demonstrated that increased uterine activity as measured by tocodynamometry can be accurately detected in the preterm parturient. More recently, Katz and Gill[8] have shown that the use of a uterine activity monitoring device in ambulatory patients at home could accurately detect uterine activity. Previous studies involving this device have been successful in predicting uterine activity and preterm labor.[5, 9] The objective of this investigation was to determine in a randomized study whether ambulatory assessment of uterine activity with use of the Term Guard system (Tokos Medical Corp., Santa Ana, California) would aid in the diagnosis

of preterm labor at an earlier time when tocolytic agents might be more effective in prolonging gestations to term.

Material and methods

Over a 9-month period women in the University of Mississippi Medical Center Obstetric Clinic were assessed for factors placing them at high risk for preterm delivery. These factors included multifetal gestations, uterine abnormalities, and the history of two or more previous preterm deliveries. Patients with historic events associated with a definite but lower risk of preterm labor (such as uterine irritability, second-trimester abortion, cervical incompetence, diethylstilbestrol exposure) were not candidates for this study. Seventy-five women >14 and <24 weeks' gestation were identified for the prospective randomized trial. All patients attended the High Risk Preterm Labor Clinic and were managed by house officers who received supervision from attending staff. Of the 75 women, six refused to enroll in the study because of the requirement of randomization. After an informed consent form was signed, the 69 remaining patients were randomized into one of two groups based on the last digit of their hospital number: those with odd numbers received the monitor and ones with even numbers were monitored by self-palpation. Two patients who enrolled were removed from the study; one aborted before the twentieth week and one moved from the area and was not available for study. This left 67 patients in the sample: 34 in the monitored group and 33 in the control group.

Subjects in both groups were given instruction regarding early signs and symptoms of preterm labor and were taught techniques of self-monitoring of uterine activity.[9] Patients were told to come to the hospital if they developed any symptoms of preterm labor (pelvic heaviness, increased vaginal discharge, back pain, rupture of the membranes, or palpable uterine contractions). All parturients were given a toll-free telephone number in the obstetric unit that was answered 24 hours each day and told to call if any questions regarding preterm labor or other aspects of pregnancy occurred. Subjects in the nonmonitored group were contacted by phone at least twice per week to assess uterine activity by palpation and patient well-being. None of the patients were told to avoid intercourse or limit their daily activities. In both groups the subjects were assessed by a gentle cervicovaginal examination every 2 weeks.

Those in the monitored group received a tocodynamometry device (Term Guard) developed for monitoring and storage of uterine activity data in the ambulatory patient. Each patient in the monitored group was instructed concerning the operation of the device and was told to monitor for 1 hour each evening and 1 hour in the morning. After monitoring the stored data were transmitted (usually in the morning) via telephone to a receiving tocograph in the center. If other symptoms (as outlined above for the control group) occurred, the patients were told to monitor for 1 hour and contact the study nurse. This device allowed ambulation during monitoring and has previously been shown to be reliable in recording even mild contractions that occur during the period of early labor.[8]

Each transmission time was approximately 6 minutes for the 120 minutes of stored data. After transmission a baseline of uterine activity was established, which usually averaged zero to three contractions per hour in each patient. If four or more contractions per hour, each lasting ≥40 seconds, were noted, the patient was asked to assume the recumbent position (left side), take hydration orally, and remonitor for an hour. If the excess uterine activity remained unabated, she was instructed to come to the hospital obstetric receiving area where a cervical examination and assessment for labor was performed.

In both groups if preterm labor was suspected, patients were admitted to the hospital receiving area and were observed by staff members unaware of the subjects' involvement in the study. If uterine activity was accompanied by progressive cervical change, a parenteral tocolytic agent was administered. These objective criteria for tocolytic therapy followed those of Zahn[10] and were applied to patients in both groups. In no subjects were uterine relaxants administered prophylactically or without cervical change. The tocolytic agent used was most often magnesium sulfate; in a few patients, ritodrine hydrochloride was employed. However, the frequency of use for either drug was equally distributed in both groups of patients.

If tocolysis was successful, patients were discharged on oral agents, bed rest (except for meals and bathroom privileges), and more frequent prenatal visits. The dosage of tocolytic drugs was adjusted to attain three or less contractions per hour in the monitored group and to abolish perceived contractions in control patients. Oral tocolysis and uterine activity monitoring were discontinued at 36 completed weeks' gestational age. Other parameters of care (particularly monitoring or nonmonitoring) remained the same as before treatment. For the purposes of this study, 36 completed gestational weeks were considered term. Pregnancies terminated before that time for reasons other than preterm labor were defined as medically indicated deliveries. Gestational age assessment was based on menstrual data, ultrasonography, and neonatal evaluation.

Statistical analysis was carried out by the use of χ^2 analysis and the Student t test. A value of $p < 0.05$ was used to designate statistical significance. Data were ex-

pressed as the mean ± the standard error of the mean.

Results

The distribution of risk factors for preterm birth was similar between the two groups (Table I).

As shown in Table II, there was no statistically significant differences in maternal age, ethnicity, or parity between the control or the monitored group. In addition, at the initial prenatal contact the patients in both groups were at a similar stage of gestation.

Of the 33 patients in the control group 22 (67%) had documented preterm labor. Of these, 15 (68%) had advanced cervical dilatation (3 cm or more) and 14 (64%) were more than 50% effaced at the time of diagnosis (Table III). In contradistinction, of the 24 (71%) patients who had preterm labor in the monitored group, only two (8%) had a cervical dilatation of ≥3 cm, and six (25%) had cervical effacement of >50% at diagnosis of preterm labor. The differences between the monitored and nonmonitored patients in cervical dilatation ($p < 0.001$) and effacement ($p < 0.01$) were statistically significant. In addition, the frequency of contractions among monitored patients who developed preterm labor was significantly increased during the last 24 hours before admission when compared to uterine activity in those who did not have preterm labor. Likewise, there were five of 22 (23%) patients in the control group who had ruptured membranes as compared to one of 24 (4%) in the monitored group.

With use of the Baumgarten Tocolytic Index[11] upon admission for preterm labor, 10 of 22 (45%) in the control group compared to 22 of 24 (92%) in the monitored group were considered to be good candidates for long-term tocolysis ($p < 0.001$) (Table IV). Although all subjects in both groups with preterm labor were treated with tocolytic agents, of those thought to have unfavorable conditions for long-term tocolysis (cervix ≥3 cm and >50% effaced), 10 unmonitored patients and one monitored patient delivered within 96 hours of admission, thus validating this method of selecting patients for tocolysis.[11, 12] Among subjects thought to be suitable for long-term tocolysis (cervix ≤2 cm and <50% effaced) in both groups, three of 10 controls and one of 22 monitored patients delivered within 1 week in spite of tocolytic therapy. Also the number of medically indicated deliveries was equal in each group (Table IV). Finally, among all patients only slightly more than half with documented preterm labor perceived their contractions.

Table III. Maternal factors at diagnosis of preterm labor

Factor	*Control group*	*Monitored group*	*p*
Preterm labor (n)	22	24	
Cervical dilation (n)			
≤2	7	22	<0.001
≥3	15	2	
Cervical effacement (n)			
<50%	8	18	<0.01
>50%	14	6	
Rupture of membranes (n)	5	1	<0.06

Monitoring in the patients with use of the tocodynamometer began at an average of 25.9 ± 2.8 weeks' gestation (Table V). This monitoring continued for 9.5 weeks (±4.1 weeks). The gestational age at which diagnosis of preterm labor was made was earlier in the monitored group (27.9 ± 2.4 weeks) versus the control group (29.4 ± 2.7 weeks). These results are not statistically different because of small sample size but approached significance ($p < 0.08$). Only 18 of the 33 (55%) patients reached 36 completed gestational weeks in the control group compared to 29 of 34 (85%) in the monitored patients ($p < 0.01$). The time gained in utero from the point of diagnosis of preterm labor was also greater in the monitored group, being 8.2 ± 2.7 weeks when compared to the control group of 4.2 ± 2.9 weeks ($p < 0.05$).

Comment

Neonatologists in their care of the low birth weight neonate have decreased morbidity and mortality but are ultimately limited by the immaturity of the infant.[1] Therefore the most critical area of concentration for perinatologists is the reduction in frequency of preterm birth. One of the most notable advances in the prevention of preterm birth has been the identification of

Table IV. Outcome data

Time gained in utero (wk)*	4.2 ± 2.9	8.2 ± 2.7

*From time of diagnosis of preterm labor.

patients at risk for this problem.[2, 4] One of the difficulties, however, associated with risk assessment for preterm birth is its poor sensitivity whereby a significant percentage of the preterm births occur in those without identifiable risk factors. Also, parturients do not always appreciate subtle uterine activity even after education about signs and symptoms of preterm labor.[5] Therefore, regardless of the education and frequent cervical examinations, many women do not perceive contractions or prodromal labor signs[6, 13] and are likely to present as unsuitable candidates for long-term tocolysis.

Often the provider cannot inhibit labor with tocolytic agents because the cervix is already too dilated and effaced for tocolysis to be effective.[3, 12] It has been pointed out that if the cervix is ≥3 cm dilated and <1 cm long, there is a 50% reduction in efficacy of tocolytic agents in postponing delivery.[11] Likewise, the incidence of rupture of the membranes increases as the cervix dilates.[3, 5] The current study confirms that early detection of preterm labor offers better candidates for tocolysis. A significantly larger proportion of women in the monitored group were treated earlier (in terms of cervical dilatation, effacement, and rupture of the membranes) when compared to the control group, although the incidence of preterm labor was similar in both groups. In addition, there was similarity in that only half of the women with preterm labor in both groups appreciated that they were having uterine activity. This probably accounts for the significant decrease in the number of women benefiting from long-term tocolysis in the control group when compared to the monitored women who were referred for treatment earlier even though they did not feel the contractions.

The outcome data in both groups also revealed a significant increase in the number of pregnancies carried to term when ambulatory uterine activity monitoring was used. In addition, the time gained in utero was nearly doubled for monitored patients when compared to unmonitored ones (Table V). The value of uterine activity monitoring in providing more reasonable tocolytic candidates appears to be the major factor in the increased number of patients reaching 36 completed gestational weeks. We are aware that daily phone contact and subsequent reassurance in the monitored patients could have contributed to the number reaching term. Those in the unmonitored group were also contacted but only twice each week. The variability of phone contact (daily versus biweekly) could be a confounding variable because increases in uterine activity should precede clinical symptoms by 24 to 48 hours.[5, 13] Nevertheless, since there is poor sensitivity by palpation and because the control patients were instructed to call the center if early signs of labor ensued, we feel it is unlikely that the more frequent nurse-patient phone contact alone greatly influenced the outcome of this study. Likewise, the enrollment criteria were very strict in this study. Undoubtably this contributed to the high incidence of preterm labor in our patients. This finding underscores the need for stringent selection criteria for those using this detection modality so that the greatest impact on preterm birth can be attained while using this device only in appropriate patients.

In summary, although the numbers are relatively small, the data in this study would point out that greater time in utero, a greater number of suitable candidates for tocolysis, and most importantly, a reduction of preterm deliveries were noted in the monitored group. This is particularly important because the patients were randomized and were comparable for the high-risk factors for preterm birth as well as for demographic statistics. It would appear that the Term Guard system is an effective method to detect preterm labor and prevent preterm delivery.

Discussion

DR. FEDERICO G. MARIONA, Detroit, Michigan. It is generally accepted that there are solid data to provide evidence that perinatal outcome has improved in the last 20 years. However, the frequency with which preterm birth occurs in this country continues unabated at a rate of nearly 8%. Delivery before 37 completed gestational weeks is tantamount to a manyfold risk for neonatal death.

Dr. Morrison and his associates attempted to demonstrate that it is possible to identify uterine hyperactivity in the ambulatory pregnant patient who carries an increased risk for preterm labor. This identification would lead to early treatment and reduction of preterm births. Indeed it is a simple and straightforward plan. One must rapidly realize, however, that the sequence that stimulates the initiation of labor in the woman is still poorly understood and uterine hyperactivity represents only one prime mover.

One of the frequent variables that alters the clinician's ability to effectively assess the patient's risk is the timing of entering into prenatal care. The population studied began care early in pregnancy (approximately 20 weeks' gestation), demonstrating that there was a clear effort to reduce the barriers to prenatal care, one important factor in effective risk assessment that must not be overlooked.

I suggest that the study is supplemented by an attempt to define endocervical bacteriology in the population at risk. In this manner another potential source of risk can be studied.

Some aspects of the study are loosely described; such as, what were the sensitivity and the specificity of the methods used in the diagnosis of preterm labor? How many visits to the obstetric unit were necessary after the program was initiated until the actual diagnosis was made?

It is interesting that a team participating in the evaluation of these patients used "intensive physical assessment" with "gentle" pelvic examinations every 2 weeks initially and more frequent visits once the patients needed tocolytic therapy. Can the authors comment on the patient's acceptance of such examinations and perhaps on the potential vagaries of using a number of house officers in the cervical evaluation, unless they were able to avoid the usual "July crisis"?

The use of bed rest, with ambulation allowed for meals and bathroom privileges, appears to be a variable that may merit future consideration. Ambulatory monitoring may not mean staying home in bed, but, if so, its effects may need separate consideration, including the thorny issue of patient compliance.

Conversely, this bed rest may be offset by more frequent visits and perhaps more vaginal examinations. The authors noted that in patients who were clinically diagnosed as candidates for long-term tocolysis, 30% of the control group and 4.5% of the monitored group were delivered before term in spite of similar clinical conditions and therapy. Are there any thoughts as to why this was so?

The patient's inability to detect the presence of contractions in more than 50% of the cases is again emphasized. Perhaps the process of education should be partially modified to place a greater index of suspicion on low pelvic pressure, back pain, changes in vaginal discharge, etc., as these have been found in our own experience, as opposed to placing a heavy emphasis on "contractions."

The authors also emphasized that intercourse was allowed to continue unrestricted. Was this advice changed after long-term tocolysis was initiated? No adolescents were entered in the study. This may reflect the characteristics of the authors' population or an effort to avoid this particular group. Indeed in our experience they represent a very special patient population who generate a number of preterm births. I will certainly expect to see some of them included in the next report.

The authors accomplished their stated goal. Uterine hyperactivity was detected earlier in the monitored group, yielding earlier access to effective tocolytic therapy and ultimately a better outcome represented by a significant difference in prolongation of gestation.

In this era of diagnosis-related groups and cost-effectiveness studies, this work represents an ideal example for a comparison of the cost of home uterine activity monitoring, including the sporadic hospitalizations, long-term therapy, missed workdays, and eventually extra help in the house versus the investment of short- and long-term caring for preterm infants. I am convinced that a relevant issue can be raised to dem-

onstrate the clear advantage of this program. Serious social implications are involved and it may even be possible to obtain the politician's attention to this issue.

If perinatologists are to make a significant change in the present rate of preterm birth and the associated perinatal loss, postponing delivery and maintaining the fetus in a safe environment until the thirty-seventh completed gestational week are the ultimate goals. We owe this effort to the next generation.

DR. WASHINGTON C. HILL, Omaha, Nebraska. Dr. Morrison and his colleagues have reported the first prospective and randomized study on the prevention of preterm birth by ambulatory assessment of uterine activity. Although home tokodynamometry has been shown in a controlled study to be of benefit, these investigators are the first to show in a prospective and randomized manner that patients who are at increased risk for preterm labor and are using ambulatory monitoring were more suitable candidates for tocolysis, had their pregnancies maintained longer, had a decreased number of preterm births, and required a fewer number of maternal and neonatal hospitalization days. Why is this important? As pointed out by Dr. Morrison, the most significant problem we as obstetricians have yet to conquer in perinatal medicine is the detection of preterm labor and prevention of preterm birth. The results of studies are controversial as to whether this can be done alone by the techniques of intensive risk assessment and patient education. The authors have taken, for the most part, a socioeconomically disadvantaged group and randomized them into those who used home tokodynamometry and those who did not. Both groups had close contact with a nurse and patient education. The monitoring of uterine activity to detect preterm labor is nothing new. What is new is the use of this device to monitor uterine activity while the patient is ambulatory and at home. Their results are impressive. I have some questions, however, for Dr. Morrison. The first question is in regards to cost. Does he have any data comparing the cost of using the ambulatory monitor versus the expense eliminated in the intensive care nursery by providing a longer time for the fetus in utero? Table III of the article showed that 23% of patients in the control group had ruptured membranes as compared with 4% in the monitored group. Does he feel that this is attributed to earlier detection of increased uterine activity in the monitored group? Table III also indicates that 67% (22/33) of patients in the control group and 71% (24/34) of patients in the monitored group developed preterm labor. Although these patients were at very high risk, this appears high. Is it a result of overdiagnosis? In Table IV of the article, 10 of 22 patients in the control group were suitable for long-term tocolysis at the time of presentation in preterm labor. This is a high percentage compared with that of most studies where it is approximately 20% to 25%. Is this a result of patient education and the daily telephone calls? Table IV also indicates that 12 of 22 and 13 of 24 patients in the control and monitored groups, respectively, perceived contractions. What does this mean? Studies to date and our own experience would suggest that patients perceive much less of their own uterine activity and the fact that patients do not perceive contractions should not be reassuring. Do Dr. Morrison and his colleagues consider this monitor an effective tool for all preterm labor patients who have risk factors? If not, just how do they decide who should use this device? Newman et al.[1] have also studied home ambulatory monitoring. They observed that normal multifetal gestations that reach term have inherently more uterine activity than a similar singleton gestation. Did Dr. Morrison observe this finding? There is little information on neonatal outcome, and ultimately all of these things are done for neonatal well-being. Could Dr. Morrison indicate whether he saw any improvement in neonatal morbidity in terms of respiratory distress syndrome, birth weight, days on the ventilator, days in the intensive care nursery, intracranial hemorrhage, etc., in the monitored group? This study may be too small to show any change in these data but do the authors have any information for us?

Dr. Morrison and his colleagues are to be congratulated on attempting to define the role of home ambulatory monitoring in the prevention of preterm birth. Although larger numbers and data from other centers will be helpful, studies to date show that home ambulatory monitoring is an effective way to detect preterm labor and prevent preterm delivery by increasing the number of candidates for effective tocolysis.

1. Newman RB, Gill PJ, Katz M. Uterine activity during pregnancy in ambulatory patients: comparison of singleton and twin gestations. AM J OBSTET GYNECOL 1986;154:530.

DR. EDUARD EICHNER, Cleveland, Ohio. I want to make some comments and commend the group that presented this paper with some data going back some 30 or 40 years ago when we first started monitoring. At that time we would not have been able to use anything like this because our procedure involved placement of electrodes into the myometrium, into the vascular tree, and into the endometrial cavity, so that part of patient cooperation was not necessary.

The other thing is that bed rest for our group with membranes that ruptured after they went home failed and labor started again in almost every patient within a day or two of being at home when she was allowed to be active.

As to the question of prolonged tocolysis, we had 100% success in those days with intravenous Relaxin, but its use was discontinued because it was too costly. Some patients had up to 7 cm of dilatation with the fetus at the +2 station. We would put the bed in a steep Trendelenburg position, and the fetus would go back into the uterine cavity and the cervix would close.

DR. L. RUSSELL MALINAK, Houston, Texas. I would like to ask Dr. Morrison, if the patients were truly ran-

domized, how can he account for the equal distribution of pathologic processes in his report?

Dr. Morrison (Closing). Dr. Mariona asked about the diagnosis of preterm labor and how many visits it took to arrive at this diagnosis. In other words, how many false negative results and how many false positive ones would be the equally important questions.

We had no false negative results. By that I mean that there were no women who had no uterine activity in this relatively small group of patients that were monitored that then came in with significant cervical dilatation. We found that an average of two patient visits was required for the diagnosis of preterm labor. Some of these cases were diagnosed, of course, on the first visit into the obstetric emergency room and some on the third or fourth visit, but about two visits was the average. So we had about a 20% rate of false positive diagnoses where the patients would have contractions and then would come in at some time and be told, "No, you are not in preterm labor." That includes the ones that went into labor and the ones that did not.

I think we cannot overemphasize Dr. Mariona's point about a cervicovaginal examination and its contribution to the prevention of preterm birth.

It is well known that the flora of the vagina, if one strips the membranes and invades the cervix, can actually cause labor. I do not have to tell many of you in this room about that system, which does work. So what we are talking about here is simply an assessment of the lower uterine segment and in general how effaced and dilated the cervix is without invading the cervix. I think that needs to be underscored.

Of course we did not do any cervical flora analysis in this study.

The other question related to why three of 10 women, who essentially were good candidates for tocolysis in the palpation group, went into preterm labor, had labor stopped, but were delivered before term. Two of those three women came back at 7 and 10 days after discharge on a regimen of oral tocolytics and experienced resumption of preterm labor. Of course they were assessing their contractions by palpation and on readmission were not good candidates for tocolysis. In other words, the cervix was more significantly dilated. Although they were again treated with intravenous tocolytics, they were delivered within a week of the second treatment.

Intercourse and bed rest were mentioned. Was intercourse interdicted after the patients went into preterm labor? The answer is yes, but we individualized that variable. In other words, if they were at home for 2 or 3 weeks and had no recurrence of contractions, then we gradually allowed ambulation and eventually intercourse. The patients were allowed to resume fairly normal activity if they were not having excess uterine activity while on a regimen of tocolytics.

Dr. Hill mentioned two interesting points. One was about expense and the other was about significant neonatal complications. Both the first and last point he derived were, I think, two of the more important points mentioned.

The expense data and the neonatal complication data will be presented at a separate time, but basically it was much more expensive to have those babies in the neonatal intensive care unit for a longer period of time. They were not being kept just for the good of the mother or anyone else. They had significant complications such as respiratory distress syndrome and necrotizing enterocolitis. In the monitored group the babies were mostly delivered at term and went to the normal newborn nursery, so they did not have many of those significant complications. Therefore we think that both expense and complications are significantly reduced.

Dr. Hill mentioned that 38% were good candidates for tocolysis in the control group, and he felt this was a relatively high figure. I think it depends on which literature you read. Some of the literature, such as the data of Papiernik et al.[1] from France, would indicate there could be even a higher percentage than that. I think that this reflects the intensive education and close follow-up by pelvic examinations these patients were given, and that is why they actually presented that often as good candidates for tocolysis.

Clearly only the patients with risk factors for preterm labor should be monitored. I think the greatest danger of this technique, like most new technologies, is that it will be over-utilized or utilized in the wrong group of patients.

There is no question in my mind that if this device is used for those who do not have high-risk factors for preterm labor, some of the "soft" indications, if you will, then it is not going to be cost effective or health effective. The message that I would leave you with on that score is that you must make sure that the patient is at high risk for preterm delivery before prescribing this device or it will be inadequately used.

I think this reflects, since we required two or more previous preterm deliveries in our group of patients, why our rates of detection of preterm labor were so high, 71% and 67%, respectively.

Also I would like to underscore Dr. Hill's comments on maternal perception of uterine activity. We did not mean to suggest that the fact that patients could feel 50% of their contractions was indicative that this was a good method of detection of uterine activity leading to preterm labor. We meant it the other way around, that is, that 50% of the patients could not significantly detect preterm labor. Half of a patient population or, by the study of Newman et al.,[2] approximately 80% of those in true preterm labor will be missed on accurate palpation to determine uterine activity that would in fact lead to preterm labor. So we do not think these signs or the percentages of women who perceive contractions are reassuring.

We agree with Newman et al.[3] that twins are associated with more uterine activity. In the patients with twin gestations we individualized the uterine activity

monitor. In other words, twins produced more activity, and sometimes we would have to raise the baseline from three contractions to five or six contractions per hour. If patients came in with four contractions an hour and did not have any cervical change in two or three assessments, we would simply raise the baseline because even twins who are delivered at term will produce more uterine activity than singleton gestations.

Dr. Eichner raised the possibility of Relaxin, and it is possibly going to enjoy a comeback. A group in St. Louis and a group in, I think, Minnesota are working with that compound now, so we may see it on the horizon as a therapeutic agent for those in preterm labor.

Finally Dr. Malinak raised the question of randomization. I really cannot say why the distribution was so equal except to say that we accepted patients on a first-come, first-served basis and randomized them. That is the way the data turned out.

We particularly looked at the six patients that refused randomization, and they were similar to our study population. I thought perhaps some of those might have skewed the data. We did have a few more twins in the monitored group when compared with the palpation group, so the groups were approximately but not exactly equal.

Braxton Hicks' contractions and motor behavior in the near-term human fetus

E. J. H. Mulder, M.Sc., and G. H. A. Visser, M.D., Ph.D.
Groningen, The Netherlands

The transient relationship between Braxton Hicks' contractions and fetal motor behavior was studied in 14 healthy nulliparous women near term. Two-hour recordings of fetal heart rate and uterine contractions and of real-time scanning for fetal body movements, breathing, and eye movements were made. The recordings were divided into state 1F and non–state 1F. Braxton Hicks' contractions were not influenced by fetal behavioral states and state changes were not related to these contractions. Fetal body movements did not stimulate contractions, but contractions coincided with a specific clustering of body movements during the ascending part of contractions. Breathing was clustered during the descending part of short-lasting contractions but decreased gradually during the long-lasting ones. Heart rate variation was increased during contractions. (AM J OBSTET GYNECOL 1987;156:543-9.)

Key words: Braxton Hicks' contractions; fetal behavioral states, fetal body movements, fetal breathing movements, fetal heart rate accelerations

More than a hundred years ago, J. Braxton Hicks[1] described the existence of periods of spontaneous antepartum uterine activity in the human. During late pregnancy the rhythmicity of these so-called Braxton Hicks' contractions constitutes a remarkably regular feature of the fetal environment in every pregnant woman. Clinically, these contractions have become important for fetal heart rate monitoring, and presence or absence of late decelerations after Braxton Hicks' contractions is considered to be an important indicator of the fetal condition. Little is known, however, as to the reaction of the normal fetus to these contractions or if the fetus itself influences the recurrence rate of these contractions by its movements.

In sheep, fetal behavioral states may be influenced by prolonged low-amplitude prelabor uterine contractions ("contractures"), often changing rapid eye movement sleep to a sleep state in which eye movements are

absent.[2] These contractures were not initiated or modified by fetal body movements.[3]

The near-term human fetus exhibits four distinct behavioral states,[4] which resemble those found in the neonate.[5] Because it is possible that in the human these frequently occurring periods of myometrial activity influence fetal behavior, we studied the temporal relationship between Braxton Hicks' contractions and motor behavior in the near-term human fetus, taking into account the fetal behavioral states. In this study we also investigated the role of fetal body movements as a possible controlling factor of myometrial activity.

Subjects and methods

Fourteen healthy nulliparous women were invited to participate in a study that combined real-time ultrasound scanning, monitoring of fetal heart rate (FHR), and recording of uterine activity. All women were outpatients with normal singleton pregnancies of 38 to 40 weeks' gestation. Subsequent delivery and outcome were uneventful; all infants were appropriate for dates (birth weight 3501 ± 465 gm, mean ± SD) and did well at and after birth.

Continuous on-line recordings lasting ≥2 hours were made between 3:00 and 6:00 PM with the women in a semirecumbent position, slightly tilted to the left. Fetal pulse (R-R) intervals were derived from abdominal electrocardiographic electrodes; they were recorded on a cardiotocograph strip chart (Hewlett Packard Model 8030 A) as beats per minute and, after having been preprocessed by means of a microprocessor, they were stored on a minicassette. These data were analyzed with the use of a computer program, of which a detailed description has been published,[6] yielding information on variations around the basal heart rate (accelerations and decelerations, expressed as the root mean square value). FHR was also recorded on an event recorder (Hewlett Packard Model 7754 A) at a paper speed of 1 mm/sec and stored on a magnetic-tape recorder (Philips, Analog-7).

Records of uterine activity were obtained with the external tocotransducer of the same cardiotocograph and written on its strip chart. The tocographic signal was, after amplification, also recorded on the event recorder and stored on magnetic tape.

Fetal activity was identified by means of two linear-array real-time scanners (Model SSD-256, Aloka Co., Tokyo, Japan, and Imager 2300, Siemens AG, Erlangen, Federal Republic of Germany). Both probes were 3.5 MHz. One observer recorded fetal eye movements; another one, fetal body and breathing movements. All types of fetal movements were recorded by means of handheld pushbuttons on the event recorder, together with the FHR and tocographic signal, and were also stored on magnetic tape. An example of a compressed 2-hour record is shown in Fig. 1. Body movements (excluding isolated limb movements, startles, and isolated movements of the head) occurring within 5 sec-

Mean	119	11.2	113.8		34.8	21.3	16.7	15.8
SEM	7	1.9	4.8		3.7	2.2	2.0	4.2

If not stated otherwise the incidence is expressed as the percentage of recording time.

onds of each other were considered to be a single movement. Their incidence was expressed as a percentage of recording time. For breathing movements apnea was defined as a pause between two breaths of ≥6 seconds. The incidence was expressed as a percentage of recording time or as the number of breaths per time unit.

Fetal behavioral states, states 1F through 4F (the suffix F indicates fetal), were identified according to the criteria of Nijhuis et al.[4] However, since states 3F and 4F are scarce, we divided the recordings only into state 1F ("quiet" sleep: stable FHR with low heart rate variability, body movements absent or incidental, and eye movements absent) and non–state 1F.

External tocography provided information on the approximate duration of the uterine contractions. Only contractions lasting ≥45 seconds were included (n = 294). These represented 81% of all observed contractions. The incidence of contractions was expressed as the percentage of recording time (total or per sleep state).

Statistical analysis was performed with the Wilcoxon signed-rank test, unless stated otherwise. The significance levels given are for two-sided tests.

Results

A total of 29 hours of observation was obtained from the 14 women. One hour (3.5% of total recording time) had to be excluded from the analysis of contractions because of incorrect placing of the tocotransducer. For two cases detailed analysis of FHR could not be performed because of poor quality of the signal (failure time >50%).

Details on the incidence of contractions, fetal movements, and occurrence of state 1F in the individual cases are shown in Table I. On average 11 contractions occurred per hour (35% of total recording time). The mean duration of the contractions was 114 seconds; 71% lasted <120 seconds; 25% from 120 to 300 seconds; and nearly 4% >300 seconds (Fig. 2).

All 14 fetuses showed at least one episode of state 1F. In total 19 of these episodes were observed, of which 16 were enclosed periods (mean duration 17.6 minutes, range 6 to 26 minutes). The fetuses spent on average 21% of recording time in state 1F. The mean incidences of body and breathing movements were 16.7% and 16%, respectively. During non–state 1F the mean duration of a single bout of body movements was 13.0 seconds (range of means among the individual fetuses from 4.4 to 24.0 seconds).

For none of the three parameters taken for comparison was a significant difference found in the incidence of uterine activity between state 1F and non–state 1F (Table II).

During the 5 minutes preceding and following each change into and/or out of state 1F, the percentage of contraction time was calculated. The mean incidence of uterine contractions in each of the four distinct 5-minute periods did not deviate largely from the mean incidence observed for the entire recording time (~35%, Table I). Neither for the changes from state 1F to non–state 1F (n = 19) nor for the changes from non–state 1F to state 1F (n = 16) was the incidence of contractions before the state change found to be significantly different from that after the change; the mean values were 33% as compared with 41% and 39% as compared with 34% of time, respectively. Moreover,

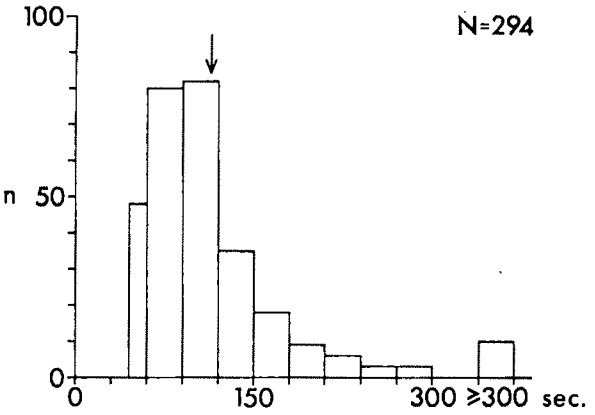

Fig. 2. Distribution of the duration of 294 uterine contractions, lasting ≥45 seconds. The mean duration (114 seconds) is indicated by the *arrow*.

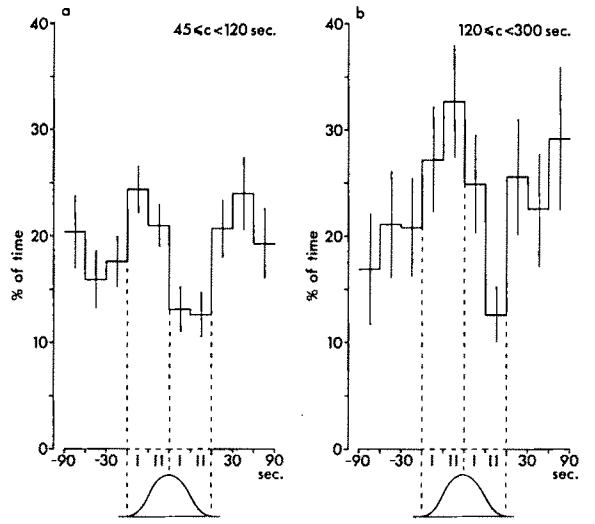

Fig. 3. Incidence of body movements before, during, and after *(a)* short-lasting (n = 123) and *(b)* long-lasting (n = 37) Braxton Hicks' contractions, occurring during non–state 1F (mean ± SEM). Both the ascending and descending parts of the contractions were subdivided into two sections of equal duration.

the incidence of long-lasting Braxton Hicks' contractions (duration between 120 and 300 seconds) and prolonged contractions (lasting more than 300 seconds) was not increased around the time of these state changes. However, the longest contraction we observed (840 seconds) was associated with a FHR deceleration, and during this contraction a change from non–state 1F to state 1F occurred.

The incidence of body and breathing movements during contractions did not differ significantly from that found between the contractions; this held both for state 1F and for non–state 1F (Table III). During the contractions, however, a specific patterning of body and breathing movements was found (Figs. 3 and 4). Body

Table II. Incidence of uterine contractions during state 1F and non–state 1F

Parameter	*State 1F*	*Non–state 1F*
No. of contractions/hr (mean ± SEM)	9.7 ± 1.9	11.3 ± 1.8
% of contraction time (mean ± SEM)	31.2 ± 5.6	33.1 ± 4.2
Duration of contractions (mean ± SEM)	114.7 ± 9.2	107.6 ± 6.3

None of the differences was statistically significant.

movements showed a clustering in the ascending part of the contraction, followed by a significant decrease during the descending part ($p < 0.01$, as compared with the ascending part). This distribution was found for both categories of contractions (Fig. 3, *a* and *b*), but the increase during the ascending part was only significant for the long-lasting Braxton Hicks' contractions ($p < 0.02$, as compared with the control period).

The number of breathing movements per 30-second epoch decreased significantly ($p < 0.05$) during the ascending part of the short-lasting Braxton Hicks' contractions but increased again as uterine activity decreased (Fig. 4, *a*). For the long-lasting contractions such a troughlike pattern was not found, but instead there was a pattern with a more or less gradual decrease in the course of the contraction, which continued thereafter (Fig. 4, *b*).

For this detailed analysis the incidence of body movements in the course of the contractions was studied only during non–state 1F ("active" sleep), whereas breathing movements were studied if they occurred during a contraction or in the 90 seconds preceding or following

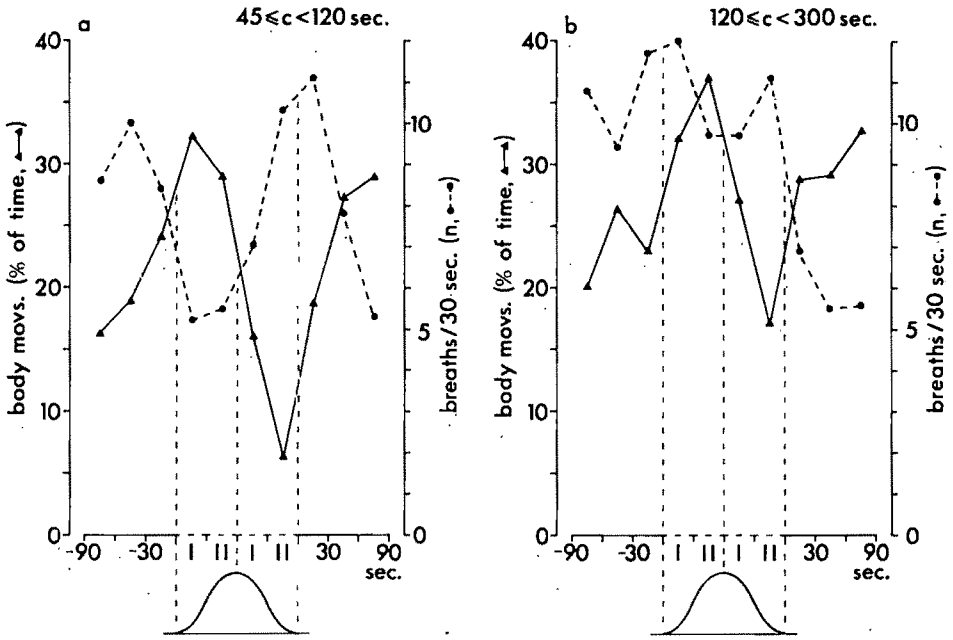

Fig. 5. Body movements and breathing movements before, during, and after *(a)* short-lasting (n = 36) and *(b)* long-lasting (n = 19) Braxton Hicks' contractions. Selected were those contractions, occurring during non–state 1F, where in the period of analysis both body and breathing movements occurred.

Table III. Incidence of body and breathing movements during and in the absence of contractions, for both behavioral states

	State 1F (% of time, mean ± SEM)		*Non–state 1F (% of time, mean ± SEM)*	
	During contractions	*Between contractions*	*During contractions*	*Between contractions*
Body movements	1.1 ± 0.6	1.3 ± 0.6	19.8 ± 2.8	19.3 ± 2.5
Breathing movements	11.9 ± 4.2	16.3 ± 5.0	16.6 ± 4.3	15.2 ± 4.0

that contraction. For those contractions that met both criteria (n = 55), a specific distribution of these movements was found (Fig. 5). An inverse relationship between the clusters of body and breathing movements was demonstrated for the short-lasting contractions (Fig. 5, *a*). The distribution patterns of body and breathing movements in the course of the long-lasting contractions (Fig. 5, *b*) were akin to those presented in Figs. 3, *b*, and 4, *b*, respectively.

Fetal heart rate accelerations (≥15 bpm; ≥15 seconds) occurred almost exclusively during non–state 1F. In the 12 fetuses in which this was studied only 2% of the accelerations occurred during state 1F. Ninety-seven of the 331 accelerations observed during non–state 1F (29.3%) started during a contraction. This approximates the percentage of time during which contractions are present in non–state 1F (33.1%, Table II); accelerations are therefore not induced by contractions. The mean duration of the accelerations that occurred during a contraction was, however, significantly longer than that of accelerations not associated with contractions (58.2 ± 3.4 and 50.3 ± 3.1 seconds, respectively, mean ± SEM; $p < 0.01$). Heart rate variation during contractions and in the first minute thereafter was significantly higher ($p < 0.05$) than during the 3 minutes preceding the contractions (Fig. 6). The percentage of accelerations that were associated with body movements was equally high during and between contractions (92.4 and 93.1, respectively; binomial test NS).

Comment

In the human, periods of antepartum myometrial activity were described by J. Braxton Hicks[1] as early as 1872. He was convinced of "the fact that the uterus possesses the power and habit of spontaneously contracting and relaxing from a very early period of preg-

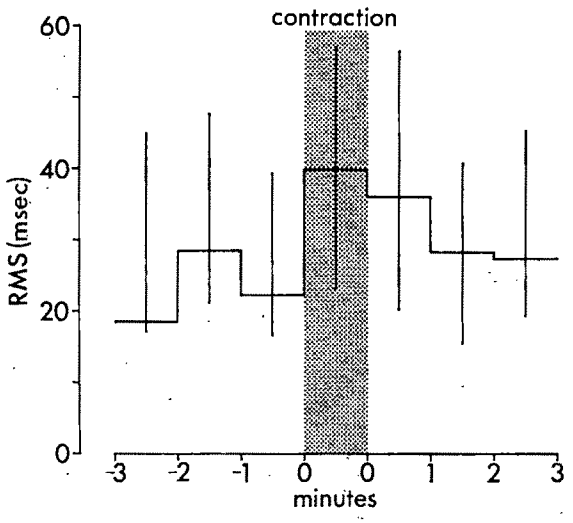

Fig. 6. Heart rate variation, expressed as the root mean square *(RMS)* value, before, during, and after short-lasting Braxton Hicks' contractions (n = 31), occurring during non–state 1F. Only those contractions that were not preceded or followed by another contraction within 3 minutes were selected for this analysis. Given are the medians and interquartile ranges.

nancy (third month)." He detected the contractions manually through the vagina and observed that they occurred every 5 or 10 minutes, sometimes even twice in 5 minutes. The duration of each contraction was generally not long; ordinarily each lasted from 2 to 5 minutes.[1]

The occurrence of antepartum uterine contractions was confirmed by Caldeyro-Barcia and Poseiro,[7] who studied intrauterine pressure by means of abdominally inserted open-tip catheters, in more than 500 women. On average, two to three contractions appeared to occur per 10-minute interval near term. This corresponds well with the incidence of nearly two per 10 minutes as found with external tocography in the present study. When placed correctly, the transducers detect contractions fairly reliably, although no information is obtained on their intensity.[8] At present, little information is available about the influences of Braxton Hicks' contractions on fetal behavior or vice versa.

In the human fetus behavioral states develop between 36 and 38 weeks of gestation. These states are distinct and mutually exclusive modes of neural activity, reflected by clusters of phenomena, which are stable over time and recur repeatedly.[5]

The period of state 1F, which is defined as a period without or almost without fetal body movements, provides us with an "in-built" control period, as we can compare periods with and without body movements in relationship to contractions in the same individual. Consequently the possible role of fetal body movements in the initiation of uterine contractions, for instance, by physical stimulation or irritation of the myometrium, could be analyzed by this study design. In turn, the possible influences of contractions on fetal activity and fetal behavioral states could also be investigated.

During state 1F the incidence of uterine contractions was the same as that during non–state 1F. This means that the occurrence of contractions (frequency, duration) is not influenced by the presence of either behavioral state. Since state 1F includes no or very few body movements, this implies also that it is very unlikely that fetal movements induce or modify contractions.

The present study shows that in the human, as in the sheep,[1, 2] prolonged contractions (lasting more than 5 minutes) do occur. On average one per 2 to 3 hours was observed. However, we could not find any influence of these prolonged contractions or of Braxton Hicks' contractions on behavioral states, as their incidences were not altered near state changes. Prolonged contractions associated with heart rate decelerations, however, change the fetal heart rate pattern from high to low variability, and in the few cases in which eye and body movements were observed, these movements also appeared to arrest temporarily.[9] Consequently it seems, in the human, that only in situations of supposed fetal hypoxemia do prolonged contractions change fetal behavioral states from rapid eye movement sleep to non–rapid eye movement sleep.

In this study we found that in both sleep states the overall incidence of body and breathing movements during contractions was the same as in between contractions. This indicates that contractions do not alter the overall incidence of these movements. There was, however, a specific patterning of both types of movements during the contractions. The decline of breathing in the first half of the contraction, followed by an increase during the descending part, was also found by Wilkinson and Robinson.[10] They suggested that this patterning might be due to distortion of the fetus, changing sensory input from chest wall and lung afferents, as was also reported in sheep.[2] On the other hand, it might well be a consequence of the patterning of body movements, as it is known that fetal breathing decreases during body movements.[11, 12] The gradual decline of breathing, which continued after the long-lasting contractions, might be related to a decreased fetoplacental exchange. The increase of body movements during the ascending part of contractions suggests a stimulation of these movements by contractions. That this does not occur during state 1F ("quiet" sleep) is in accordance with an earlier study that showed that neither body movements nor heart rate accelerations are induced by external physical stimulation of the fetus through the maternal abdominal wall[13] and with the fact that neonates are difficult to arouse during quiet sleep. In the fetus bursts of movements occur at more or less regular intervals of about 1 minute.[14] It is there-

fore understandable that an increase of movements during the first half of the contraction is followed by a decrease afterward, resulting in an equal overall incidence of body movements during and between contractions.

The relationship between heart rate accelerations and body movements found in this study, is in agreement with reports in the literature.[11, 15] Heart rate accelerations are often followed by transient decelerations.[11] The patterning of body movements during the contractions might therefore explain the transient increase in heart rate variation. The longer duration of the accelerations during contractions suggests, however, that other mechanisms might also play a role. One may think in terms of qualitative changes in body movements (more forceful) or of compensatory heart rate changes induced by the transient reduction in fetoplacental exchange during the contractions.

It is concluded that in the near-term human fetus: (1) Braxton Hicks' contractions are not influenced by behavioral states, and state changes are not related to these contractions; (2) body movements do not stimulate contractions; (3) contractions coincide with a specific clustering of body movements and breathing movements.

We thank K. T. Meijer for his expert technical help. Our thanks are also due to Dr. A. Boogert for the critical reading of the manuscript and to Y. Lems for the illustrations.

(Sub)Specialization in obstetrics and gynecology: Results of a survey by The American Board of Obstetrics and Gynecology

James A. Merrill, M.D.
Seattle, Washington

Survey of department chairmen (n = 113) and former fellows (n = 599) revealed that from 1974 to 1984 the mean number of full-time faculty doubled and the increase was in subspecialists (5.1 per department). More than 60% of departments report trained subspecialists in three areas and 92.9% in one or more areas. Twenty-two chairmen report zero laboratory research funding. Of former fellows, 82% are certified in obstetrics and gynecology; 44% are certified in a subspecialty; 86.3% have passed the subspecialty written examination. Employment is full-time faculty for 60.8% and full-time private practice for 16.1%. They devote 49.1% of professional time to the subspecialty and 15.9% to research, most of which is clinical; 56.6% spend no time in laboratory research. While 40.3% have submitted no research grant applications since completion of fellowship, of all grants submitted to the federal government, 63.5% were approved and 34.5% were funded. The mean number of papers published since fellowship is 7.8. The number of fellows graduating may meet estimated need. The initial objectives of this new certification are being achieved. (AM J OBSTET GYNECOL 1987;156:550-7.)

Key words: Subspecialization, specialization, obstetrics and gynecology, survey

The American Board of Obstetrics and Gynecology was incorporated in 1930 and the first specialists in obstetrics and gynecology certified. The board continues to be interested in the nature of physicians who enter obstetrics and gynecology, the quality of education they receive, and the impact of the evaluation processes of the board. In 1969 the board convened a conference on specialization, attended by representatives of national societies in obstetrics and gynecology. The purpose of the conference was to improve the health care of women by elevating standards of education. The conference was followed by thorough study of the impact of advanced training in obstetrics and gynecology. An outgrowth of this was the formation, in 1972, of three specialty divisions of The American Board of Obstetrics and Gynecology for (1) gynecologic oncology, (2) reproductive endocrinology, and (3) maternal-fetal medicine.

The general objective of the specialty divisions was to improve the health care of women with special problems by: (1) elevating standards of education, (2) enhancing the recruitment of qualified physicians, (3) improving the organization and distribution of patient care, and (4) increasing basic knowledge. Although not specifically stated, many assumed that "increasing basic knowledge" would result from increased research activities of specialists certified for special qualification.

Criteria and mechanisms were established for approval of specialty fellowships. Each is periodically reviewed by the Board. By 1985 there were 161 approved fellowship programs (29 in gynecologic oncology, 50 in reproductive endocrinology, and 82 in maternal-fetal medicine). In 1974 the first examinations were given and certificates of special qualification were issued. By the end of 1985 there were 896 diplomates who had been awarded certificates of special qualification in one of the three specialty areas (364 in maternal-fetal medicine, 294 in gynecologic oncology, and 238 in reproductive endocrinology).

At 10 years after the first certificates of special qualification were granted, the Board was interested in studying the results of this new specialty certification. Many of the original objectives seemed to have been accomplished. However, concern had been expressed that research in obstetrics and gynecology may have been diminished by substitution of clinically oriented specialty training programs for the laboratory training that otherwise might have been pursued by those entering academic careers. Therefore three studies were conducted by the board addressing these concerns. One was of the scholastic ability of residents in obstetrics and gynecology completing their training in 1983 and 1984. Reported here are analyses of a questionnaire sent to all who had ever been enrolled in a board-approved specialty fellowship and a questionnaire sent to all chairmen of medical school departments of obstetrics and gynecology.

Method

In 1984 the two questionnaires were sent out. A questionnaire designed to obtain information regarding laboratory research activity in medical school departments of obstetrics and gynecology and the impact of specialty fellowship training was sent to 144 chairmen of departments of obstetrics and gynecology in the United States and Canada. The second questionnaire designed to identify activity profile, with emphasis on laboratory research, was sent to the 869 individuals who had started a Board-approved fellowship prior to 1982, thus to those presumably who had completed fellowship prior to 1984. (In fact, seven respondents indicated they started their fellowship in 1982 and two respondents indicated that they started in 1983.) The data were compiled, analyzed, and made available by the Division of Research in Medical Education, University of Washington, School of Medicine, Seattle, Washington.

Response

The response was good. The questionnaire was completed and returned by 116 department chairmen (80.6%). The questionnaires from 113 chairmen (78.5%) including 108 from the United States were used in the analysis. Questionnaires were received from 614 former fellows (70.7%). The responses from 599 (69.2%) former fellows were used in the analysis. The only questionnaires excluded from the analyses were those received after computations had been initiated. There were a few questions with no responses in one or more instances and some completed the questionnaire but did not identify their specialty area.

Findings and results

Chairman questionnaire. Between 1974 and 1984 the number of full-time faculty in departments of obstetrics and gynecology nearly doubled (Table I). Although 17.9% of departments in 1974 had no M.D. full-time faculty, in 1984 the mean number per department was 12.6. The increase in full-time faculty has resulted from appointment of individuals with special qualification in the specialty areas of obstetrics and gynecology (Table II). The mean number of trained subspecialists per department is: reproductive endocrinology, 1.4; gynecologic/oncology, 1.4; maternal-fetal medicine, 2.3. There are about half again as many individuals in departments with subspecialty interest who have not completed approved specialty fellowships. Table III shows that only 7% of departments do not have any faculty member who has completed a specialty fellowship. More than 60% of departments report fellowship-trained specialists in all three areas; 23.9% in two areas; and almost 9% in one area only. The proportion and number of fellowship-trained specialists in medical school departments of obstetrics and gynecology are increasing.

Table I. Number of full-time faculty (mean per department)

	M.D.	*M.D. and Ph.D.*	*Ph.D.*
In 1974	6.6*	0.4	1.1
In 1984	12.6	0.7	2.3

*17.9% of departments had none.

Analysis of the questionnaire suggests that laboratory research activity in departments of obstetrics and gynecology is not flourishing. Almost one third of chairmen (29%) indicated they could not allocate research laboratory space to a new faculty member and 40.4% of the chairmen indicated that no one had been trained in laboratory research in the department during the previous 10 years. As expected, laboratory research support, in order of dollar amount, decreases from federal government to foundations, practice revenues, industry, and university. For each of these categories of funding, more than 25% of the schools indicate no laboratory research funding. There were 22 department chairmen who reported zero laboratory research funding from all sources combined. The chairmen were asked if they plan, within the next 5 years, to recruit new faculty who will devote more than 50% of their time to laboratory research. Table IV demonstrates that 53.6% of the responding chairmen do not plan to recruit an M.D. to do laboratory research. The data indicate that Ph.D.'s are being recruited for research more often than M.D.'s. The mean number of new faculty being recruited for research in the next 10 years is two per school.

The response from chairmen suggests satisfaction with the current number of trainees in obstetrics and gynecology. Table V indicates that slightly more than half of the chairmen recommend that the number of trainees in fellowships and residencies remain stable. Of the respondents, 32.5% recommend an increase in maternal-fetal medicine fellows and 41.5% recommend a decrease in the number of residents.

The chairmen indicated their opinion that the most frequent factors with negative impact on a young faculty member pursuing a career in laboratory research were personal preference and volume of clinical practice.

Fellows questionnaire. Table VI records the specialty area of the 599 respondents whose data were used in the analysis. All of the respondents began a fellowship, but not all of them completed it. Table VII, which displays the date training was completed, shows the growth of fellowship programs, which began in 1973 and increased erratically through the years covered by

Residents	13.2	41.5	45.3

Nonrespondents were maternal-fetal medicine, five; gynecologic oncology, four; reproductive endocrinology, five; residents, seven.

the survey. There has been no increase in number of programs or number of fellows in recent years. On the basis of the number of fellows who have recently graduated and those currently enrolled in fellowship there appears to be a plateau in the number of physicians completing fellowship at the current rate of 12.8% of the annual graduates from obstetrics and gynecology residencies.

Table VIII reveals that 82% of those responding to the question were certified diplomates in obstetrics and gynecology with almost 85% of gynecologic oncologists certified. If it is assumed that those who did not respond to this question are not certified, then 79.6 of the total respondents are certified. The percent certified in obstetrics and gynecology is no less than the number estimated to be eligible for certification, on the basis of the dates when fellowship was completed. In fact, only 76.3% of respondents indicated that they completed fellowship prior to 1983. Certainly some of those who did not complete fellowship have gone on to be certified in obstetrics and gynecology.

Tables IX and X display the success of the respondents in the specialty certifying process. It seems reasonable to assume that successful candidates were more likely to return the questionnaire than were unsuccessful candidates. This would have a enhancing affect on the results. Those respondents who completed fellowship in 1981 or before could have been eligible for certification of special qualification in one of the three specialties at the time of the survey, and 64% of the respondents were in this category. The survey reveals that only 44% of the respondents have been certified

Table VIII. Certified in obstetrics and gynecology

	n	*Certified*	*Percent of respondents to this question*	*Percent of total respondents*
Maternal-fetal medicine	237	192	81	78.4

Gynecologic oncology	152	129	84.9	83.2
Total	582*	477	82.0	79.6
Nonrespondents	17			

*Includes those not indicating subspecialty (n = 7).

for special qualification (Table IX). The percent certified in gynecologic oncology exceeds that for the other two specialties. There are a number of individuals who have passed the written examination and are no longer eligible to take the oral examination. Table X indicates that 86% of those who answered the question indicated that they had passed the written examination in the specialty. If we assume that those who did not respond to this question have not passed the written examination, then the figure drops to 80%. On the basis of the date of completing fellowship, it could be estimated that 92% were eligible to have passed the written.

The majority of individuals who entered a fellowship are now full-time faculty members (Table XI). Overall, 60.8% of 595 respondents indicate that their current employment is as a full-time faculty member (slightly less for gynecologic oncologists). Approximately 16% are employed full-time by a hospital other than the medical school and an equal number are in full-time private practice. For those completing fellowship during recent years, the percent in private practice is somewhat lower and the percents in full-time medical school and full-time hospital are both slightly greater. However, there is no great difference between those completing fellowship in 1976 and those completing in 1983.

Those who have taken fellowship training indicate that almost one half of their professional time is devoted to the clinical area of their specialty (Table XII). Gynecologic oncologists devote 60% of their time to oncology, whereas those in the other two specialties devote slightly less than half of their time to the specialty. Thus some portion of time is devoted to the breadth of the specialty by individuals with fellowship training.

The mean for the percent of time devoted to research is 15.9% while the mode and median time devoted to research is 10%. Those in reproductive endocrinology devote the greatest amount of time and those in gynecologic oncology the least amount of time to research. Most research appears to be clinical research. This is most apparent for those in gynecologic oncology. The percent of research time devoted to laboratory research is 13.3% for gynecologic oncology; 19.0% for maternal-fetal medicine and 29.1% for reproductive endocrinology, according to the response to this question. From this, it is possible to conclude that the percent of total professional time devoted to laboratory research is 1.4% for oncology; 3.0% for maternal-fetal medicine; and 6.0% for reproductive endocrinology. The response indicates that 56.6% spend no time in laboratory research.

Total	599*	261	43.6

*Includes those not indicating subspecialty (n = 3).

One measure of research productivity is the number of research grants submitted. Experience with research grant applications is displayed in Tables XIII to XVII. The survey revealed that 32.8% of individuals have submitted research grants to the federal government and slightly fewer have submitted research grants to each of the other sources of funding (Table XIII). Thus a significant number of former fellows answered that they had not submitted a research grant application. Approximately 40% of the respondents indicated that they had filed no research grant applications since completion of training, and 85.8% have not had a research grant funded by the federal government. Specialists in reproductive endocrinology most frequently and specialists in gynecologic oncology least often have submitted research grant applications. Table XIV reveals that the 599 respondents have submitted 1478 research grant applications. The mean number of grants submitted per respondent is <1 to each of the five funding sources listed and 2.5 to all sources combined. However, the mean number of grants submitted, for the individuals submitting any grants, ranges from 2.29 for the federal government to 1.72 for the university (Table XV). Those who submit grants have submitted multiple grants over the years (mean 4.1).

The success of submitted research grants is quite re-

spectable, as seen in Tables XVI and XVII. Of all the grants submitted to the federal government, 63.5% were approved and 34.5% were funded. The success was greater for those grants submitted to other funding sources. Table XVII reveals that 809 grants have been funded at a dollar value per funded grant ranging from $37,812 for oncology to $67,295 for maternal-fetal medicine.

The former fellows were asked who should carry out most laboratory research in their specialty and responded as follows: Ph.D., 29.9%, M.D., 13%, M.D., Ph.D., 26.4%; whomever has the interest and skills, 30.6%. When asked if they were satisfied with the amount of time devoted to laboratory research, 48.5% responded yes. There was very little difference in the response from the three groups: maternal-fetal medicine, 50.2%; reproductive endocrinology, 47.3%; gynecologic oncology, 49.4%.

The mean number of papers published in refereed journals was 7.8 (Table XVIII). There were 23.9% who reported that they had published no papers. There was no trend identified with respect to the year in which the training was completed.

As was true for the chairmen, Table XIX indicates that the majority of respondents believe that the number of trainees in their specialty should remain stable or decrease. Very few recommended an increase in number of trainees.

Comment

Although response was good, it was not 100% and conclusions from the survey must be made with that in mind. Both questionnaires emphasized laboratory research. It is possible that those who did not respond were influenced in one way or another by that. The respondents did provide some very specific financial information relating to research.

In 1983 The Association of Professors of Gynecology and Obstetrics and The American College of Obstetricians and Gynecologists surveyed all chairmen of de-

partments of obstetrics and gynecology[1] and found the mean number of M.D. and Ph.D. faculty per department to be identical to results of this survey. The APGO/ACOG survey reported an increase in the number of subspecialty faculty and a decrease in general obstetrics and gynecology faculty during the preceding 3 years. This trend is also apparent from the Board study. From 1974 to 1984 the mean number of M.D. faculty per department increased by 6. In 1984 the mean number of faculty with Board-approved fellowship training was 5.1 and there were other subspecialty faculty without fellowship training. The APGO/ACOG survey identified 448 full-time faculty certified in one of the three specialty areas, whereas the current study identified 571 full-time faculty with approved fellowship training. The increase in number is greater for maternal-fetal medicine and reproductive endocrinology than for oncology. The 1983 survey identified 13 schools with no full-time faculty certified for special qualification and the Board survey identified only eight schools without trained subspecialists. Those certified early did not have Board-approved fellowship training and many former fellows are not yet certified.

Pearse et al.[1] reported a greater percent of certified subspecialists with full-time faculty appointments (reproductive endocrinology, 84%; maternal-fetal medicine, 78%; gynecologic oncology, 63%) than was found for former fellows in the board survey. The difference might be explained if those who achieve certification are employed more often as full-time faculty than those who are not certified. There is no other evidence for this.

Table XV. Research grant applications submitted (mean per individual for those submitting any grants)

	Mean
Federal government	2.3
Foundations	1.9
Industry	2.3
University	1.7
Practice revenue	1.8

The APGO/ACOG survey reported that research faculty needs were projected to increase by 53%, which certainly was not the case in the Board survey. In the APGO/ACOG survey, chairmen indicated a need to add approximately four full-time equivalent faculty positions per department for full-time research by 1988. The Board survey indicated plans to recruit approximately two new faculty during the next 10 years who will devote more than 50% of their time to laboratory research (one full-time equivalent). This may reflect the difference between plans for laboratory research and clinical research and also the impact of the growing need to finance departments from clinical practice revenue.

Although former fellows devote some time to the breadth of the discipline, the majority of their time is devoted to their specialty area. Whereas essentially all

subspecialists who are eligible have been certified in obstetrics and gynecology and most have passed the specialty written examination, it may be surprising that only 44% of the respondents are certified in their subspecialty. The requirement of a current published article influences that. Recent Board policy changes may decrease the number of individuals who pass the specialty written examination but never achieve eligibility for the oral examination.

The future need for diplomates certified for special qualification is uncertain. The response from both chairmen and subspecialists does not indicate a strong desire to increase the number of fellows in training, although some chairmen indicate a need for increased numbers. The 1983 APGO/ACOG survey projected a need for 414 new subspecialists by 1988: 164 in maternal-fetal medicine, 114 in gynecologic oncology, and 136 in reproductive endocrinology. Such numbers could be met by those currently being certified only if nearly all accepted full-time faculty appointments. In 1972 the American Board of Obstetrics and Gynecology surveyed all certified obstetrician-gynecologists in the United States. In that survey,[2] 14.1% of 9297 respondents indicated that there was an area of obstetric-gynecologic practice in which a majority of their practice time and effort was being devoted, and 10.2% indicated one of the three current divisions (maternal-fetal medicine, 4.7%; gynecologic oncology, 2.9%; and reproductive endocrinology, 2.6%). By 1985 the 896 diplomates with certificates of special qualification represents 3.9% of the approximately 22,700 living diplomates. Certificates of special qualification were issued to 158 diplomates in 1984 and 1985, which represents 7.2% of diplomates certified in the same years. The number of fellows graduating in 1985 and 1986 represents 12.8% of the total number of residents who graduated in 1983 and 1984. This suggests that current subspecialty training approximates practice need. There have been no formal studies of the demand for subspecialists, but estimates based on the 1972 board survey,[2] identified patient problems in the state of Colorado (E. S. Taylor), and projections for development of tertiary care centers (W. H. Pearse) each have suggested a need for 300 to 400 specialists in reproductive endocrinology and gynecologic oncology and 700 to 800 in maternal-fetal medicine. There has never been an effort to establish a desired number of specialty fellows. Despite that, the number of fellows graduating annually has plateaued and is approximately what several have estimated the need to be. It is possible that such estimated needs will be met by the end of the century.

One objective of the questionnaire was to determine the impact of subspecialization on research, with em-

phasis on laboratory research. The median and mode for percent of professional time devoted to research was 10% with a mean of 15.9%. The mean for reproductive endocrinology was higher (20.5%). Most research is clinical research. The percent of total professional time devoted to laboratory research varied from 1.4% for oncology to 6% for reproductive endocrinology. Although 40% of respondents have never filed a research grant application, the success of the many submitted research grants is good. Of all research grants submitted to the federal government, for example, 34.5% were approved and funded. Total research funding to these former fellows is $43,279,000.00. Certainly this has increased the research productivity of medical school departments of obstetrics and gynecology.

Thus the survey reveals that research is not the major activity of subspecialists. Undoubtedly there are many reasons for this and one may be the nature of those who have entered obstetrics and gynecology. The Board studied the scholastic ability of those who finished obstetrics and gynecology residencies in 1983 and 1984. To the extent that scholastic ability is measured by performance on National Board of Medical Examiners Part I and Part II examinations, residents in obstetrics and gynecology, on the average, had slightly less of that ability than national norm groups who took the same examinations.

Ten years after the first certificates of special qualification were granted, it appears that the objectives of this new certification by the Board are being achieved. Qualified physicians have been recruited into the special areas of obstetrics and gynecology and more than 60% have full-time medical school faculty appointments. Almost all departments have one or more trained subspecialists. The fellowship training programs are regularly reviewed and have structured required curricula to ensure appropriate training of fellows. Those who have been trained devote more than half of their time to the specialty area but most are not removed from the principal discipline. The development of divisions within departments of obstetrics and gynecology has elevated the standards of education in each of the special areas and contributes to improvement in the organization and distribution of patient services. Although subspecialists devote most of their time to clinical activities, they are involved in laboratory research that increases basic knowledge in the special areas. It is difficult to separate the impact of newly emerging technology and knowledge from the impact of advanced training.

I gratefully acknowledge the assistance of Doug Schaad, M.Ed., Division of Research in Medical Education, University of Washington School of Medicine, Seattle, Washington.

The diagnostic value of hysterosalpingography and hysteroscopy in infertility investigation

Jamil A. Fayez, M.D., Ghazi Mutie, M.D., and Peter J. Schneider, M.D.
Winston-Salem, North Carolina

Four hundred infertile patients had hysterosalpingography and hysteroscopy as part of their infertility workup. A comparison between the findings of these two procedures was carried out to study their diagnostic value in female infertility investigation. It was found that hysterosalpingography was as accurate as hysteroscopy in the diagnosis of normal or abnormal uterine cavities while the nature of the intrauterine filling defects was accurately revealed by hysteroscopy only. It is concluded that hysterosalpingography is an important screening procedure for the diagnosis of normal or abnormal uterine cavities and that hysteroscopy should be reserved only for the confirmation and treatment of intrauterine anomalies discovered by hysterosalpingography. Therefore we look at the two procedures, hysterosalpingography and hysteroscopy, as complementary techniques. (AM J OBSTET GYNECOL 1987;156:558-60.)

Key words: Hysterosalpingography, hysteroscopy, infertility

Hysteroscopy was first performed more than 100 years ago,[1] but the procedure was practiced by few physicians until recently. With advances in instrumentation and the availability of better distention media, interest in hysteroscopy has increased, particularly with regard to its applicability in the investigation of female infertility.[2] Reports on the diagnostic value of hysteroscopy are conflicting, with many authors claiming increased accuracy of hysteroscopy compared with hysterosalpingography in the diagnosis of intrauterine lesions.[3, 4] Some authors[5, 6] have suggested that hysterosalpingography should be completely supplanted by endoscopy. In this context, it was thought to be appropriate to make this retrospective study about hysterosalpingography and hysteroscopy to determine the diagnostic value of each procedure and to establish certain criteria whereby each might be properly used.

Material and methods

The study population consisted of 400 women between the ages of 17 and 40 (mean 29.2) who had a complete infertility workup, including hysterosalpingography and hysteroscopy. Hysteroscopy was performed routinely for most infertile patients who had diagnostic or operative laparoscopy. Whether diagnostic or operative, hysteroscopy always followed laparoscopy to avoid instillation of contrast medium into the pelvis, which could have interfered with any operative laparoscopy procedures. All patients who had operative hysteroscopy were included in this study while those who had diagnostic procedures were selected randomly. All charts were reviewed to compare the diagnostic value of hysterosalpingography and hysteroscopy in the investigation of female infertility. Hysterosalpingography preceded hysteroscopy by 1 to 6 months in all cases; the interval depended on the indication of hysteroscopy on the basis of history and physical examination as well as the findings of hysterosalpingography.

All hysterosalpingographic examinations were outpatient procedures and they were performed and interpreted by a reproductive endocrinologist in conjunction with a radiologist. They were performed in the proliferative phase of the menstrual cycle with sterile techniques and without analgesia or anesthesia. Water-soluble contrast medium, 10 to 20 ml (Sinografin, E. R. Squibb & Sons, Princeton, New Jersey), was injected slowly into the cervical canal via a plastic acorn with the aid of fluoroscopy monitoring. In the majority

Table I. Indications for hysteroscopy

Indication	*No.*	*%*
Routine infertility workup	177	44.25
Unexplained infertility workup	43	10.75

Table II. Uterine findings at hysterosalpingography and hysteroscopy

Uterine finding	*Hysterosalpingography*	*Hysteroscopy*
Normal uterine cavity	194	219 (194 + 25)
Synechiae	96	82
Arcuate uterus	26	20
Double uterus (septate or bicornuate)	24	24
Polyps	16	9
Fibroids	10	12 (10+ 2)
Diethylstilbestrol-associated uterus	34	34
Total	400	400

of cases two anteroposterior films were sufficient to allow the diagnosis of uterine or tubal abnormalities.

Hysteroscopy was performed in the proliferative phase of the menstrual cycle with the patient under general anesthesia with endotracheal intubation. Although local anesthesia is adequate for diagnostic hysteroscopy, it was not feasible here as all hysteroscopy procedures were combined with diagnostic or operative laparoscopy. Hyskon (Pharmacia Laboratories, Inc., Piscataway, New Jersey) was the only distention medium used with an average of 40 ml needed for diagnostic purposes and 150 ml for operative procedures. Once the uterine cavity was adequately distended, a systemic exploration was performed. The fundus was examined first; then the anteroposterior and lateral walls were scrutinized. Before the procedure was completed, both ostia were identified and the cervical canal was thoroughly scanned. Findings were recorded on a hysteroscopic examination form for future review. The indications for hysteroscopy in this study are shown in Table I.

Results

Synechiae were easily identified by hysteroscopy as bridges extending from one part of the uterine cavity to another. The arcuate uterus was identified hysteroscopically by the shallow and smooth fundal wedge protruding into the uterine cavity. The septate and bicornuate uteri were differentiated by the laparoscopic appearance of their fundi and then examined hysteroscopically. The septum in the septate uterus appeared triangular with a thin apex in contradistinction with the thick, broad and short muscular partition in the bicornuate uterus. All of the 12 fibroids were single and sessile. Nine of these were ≤ 3 cm and were extracted hysteroscopically with bleeding minimized by the pressure of the bulb of a Foley catheter. The other three fibroids were ≥ 5 cm and were removed abdominally. When the 34 diethylstilbestrol-associated uteri diagnosed by hysterosalpingography were examined hysteroscopically, they showed different abnormalities including small uterine cavities, multiple short synechiae, intracervical ridges, and short or long cervical canals.

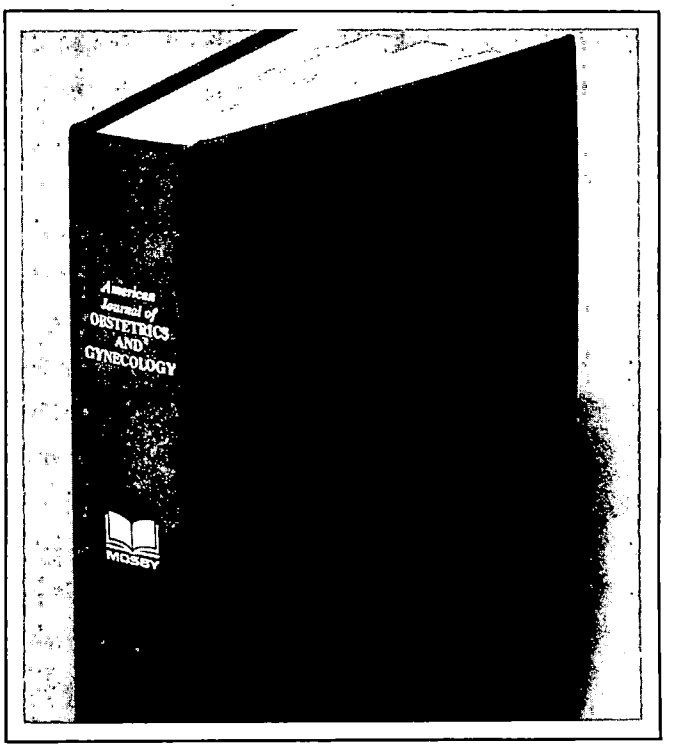
Table II shows that hysterosalpingography was as accurate as hysteroscopy in the diagnosis of normal uterine cavities, double uteri (septate and bicornuate), and diethylstilbestrol-associated uteri but was inaccurate in 27 cases belonging to the remaining subgroups. Hysterosalpingography showed synechiae in 96 patients while hysteroscopy confirmed the diagnosis in only 82. Sixteen patients were diagnosed as having polyps; five of these proved to be mucus or thick shaggy endometrium when visualized by hysteroscopy and two were small fibroids. A χ^2 test showed that there was a significant difference in the accurate diagnosis of uterine synechiae when made by hysteroscopy ($p \leq 0.002$) while the difference was not significant in the diagnosis of other uterine anomalies made by the two procedures ($p \geq 0.05$).

Comment

Procedures to determine whether a uterine factor is responsible for infertility include endometrial sampling, endometrial culture, hysterosalpingography, hysteroscopy, and laparoscopy. Hysterosalpingography is a simple, noninvasive procedure that enables visualization of the uterine cavity contour, revealing or ruling out anomalies that include different types of intrauterine defects. For centuries, hysterosalpingography was the sole procedure that could provide adequate information about the normality or abnormality of the uterine cavity. Hysteroscopy, the direct visualization of the interior of the uterine cavity, was, until the early 1970s, of controversial value. Most recently, hysteroscopy has developed into a highly sophisticated and effective technique with increasing applicability. While studies[5,6] have demonstrated the increased accuracy of hysteroscopy over hysterosalpingography in the diagnosis of intrauterine lesions, others found that hysterosalpingography was more reliable.[4] Over the years, we have been impressed with the positive correlation between the findings of hysterosalpingography and those of hysteroscopy. Therefore this retrospective study was made to compare the diagnostic value of each of these two techniques in view of the conflicting reports regarding which procedure has the advantage over the other.

The results of this study demonstrate that both hysterosalpingography and hysteroscopy constitute valuable methods in the investigation of infertility. Table II shows that there is no statistical difference in the diagnosis of uterine abnormalities by either hysterosalpingography or hysteroscopy. The conflict between the results of this study and those of others is probably due to difference in techniques and interpretations. Our patients were thoroughly counseled regarding the details of hysterosalpingography to reduce tension that would have contributed to uterine spasm. It is known that contrast material may induce localized uterine spasm that may resemble an intrauterine defect.[7] This problem was avoided in this study by injecting the dye slowly but steadily without interruption until the procedure was completed. In contrast to many practices where hysterosalpingography is performed and interpreted by radiologists, ours were performed or supervised and interpreted by the senior author (J. A. F.) in conjunction with a radiologist. All these precautionary measures might have contributed to the correct diagnosis obtained by hysterosalpingography in this study.

Differential diagnosis of an intrauterine filling defect includes air bubbles, mucus, polyps, submucous fibroids, intrauterine synechiae, a septum, and, rarely, asynchronous uterine contractions. Hysterosalpingography can easily detect these abnormalities and in the majority of cases reveals the nature of the intrauterine defects as shown in Table II. The few discrepancies between the diagnosis obtained by hysterosalpingography and those obtained by hysteroscopy are expected since hysterosalpingography localizes the defects while hysteroscopy makes them directly visualized. An average hysteroscopist may confuse one type of intrauterine defect with another. Endometrial fragmentation or incomplete shedding can mimic synechiae. Extra care must be taken to differentiate polyps from thick shaggy endometrium or from myomas. The polyp has a rounded, smooth free end, while thick strips of endometrium have a shredded appearance and can be easily dislodged by gentle strokes with the end of the hysteroscope. Myomas can be easily distinguished from polyps as the latter have gentle undulations as the pressure of the distending medium varies.



It is obvious from this study that hysterosalpingography is very reliable in the diagnosis of uterine abnormalities. In addition to this diagnostic value, hysterosalpingography does provide information about tubal patency or blockage. Another benefit of hysterosalpingography that most gynecologists must have experienced is the therapeutic effect of hysterosalpingography.[8]

Because hysterosalpingography is a much less invasive procedure than hysteroscopy and because of the valuable information it provides about the uterine cavity and tubes, hysterosalpingography should be mandatory in the evaluation of infertility and recurrent pregnancy loss. When an intrauterine abnormality is detected, it is obvious that the nature of the lesion should be identified by direct visualization and dealt with by operative hysteroscopy. If hysterosalpingography fails to demonstrate any intrauterine abnormality, then hysteroscopy becomes a controversial issue. We believe that hysteroscopy should not be considered as a part of the routine infertility workup, but, after a complete infertility workup and when no apparent cause is found, laparoscopy combined with hysteroscopy is essential for the completion of the investigation. The yield of the combined approach in patients with unexplained infertility is high.[9]

Here's what MOSBY'S BOUND VOLUMES can add to your practice!

MOSBY
TIMES MIRROR

Handsomely bound in durable buckram with rich gold stamping, bound journal reference volumes are important to every successful practice.

- gives quick and easy access to important journal articles
- eliminates problems with missing issues or pages
- makes your regular subscription a "working" copy to mark up, tear from, or file
- offers an inexpensive and easy way to guarantee bound reference volumes—prices include shipping

You Must Order Now!
Bound volumes are made up from over-run copies of each journal issue. You never worry about sending out your personal copies. But over-run quantities are limited. We need your order today! Bound volumes are only available to current subscribers and may not be ordered in place of a regular journal subscription. Payment must accompany your order.

gainst the *B. fragilis* group?

the facts still favor Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

The *Bacteroides fragilis* group includes *B. fragilis, B. distasonis, B. ovatus, B. thetaiotaomicron, B. vulgatus.*

The percentages displayed are a weighted average of the susceptibilities reported for these organisms at an MIC breakpoint of 16 mcg/mL by the Antibiotic MIC Susceptibility Reports, National Summary, in *The Bacteriologic Report: Volume I 1986,* Totowa, NJ, BAC-DATA® Medical Information Systems, Inc. This average was weighted by the frequency of isolation of each organism.

NOTE: *In vitro* activity does not necessarily imply *in vivo* effectiveness.

MEFOXIN is contraindicated in patients who have shown hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

MEFOXIN is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Streptococcus faecalis*) and many strains of *Enterobacter cloacae.* Methicillin-resistant staphylococci are almost uniformly resistant to MEFOXIN.

For a Brief Summary of Prescribing Information, please see following page.

MSD
MERCK SHARP & DOHME

Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:

LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae* (formerly *Diplococcus pneumoniae*), other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli, Klebsiella* species, *Hemophilus influenzae*, and *Bacteroides* species.

GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli, Klebsiella* species, *Proteus mirabilis*, indole-positive *Proteus* (i.e., *P. morganii, P. rettgeri*, and *P. vulgaris*), and *Providencia* species. Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).

INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli, Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ and *Clostridium* species.

GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli, N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.

SEPTICEMIA caused by *Strep. pneumoniae* (formerly *D. pneumoniae*), *Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli, Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group.§

BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis*, streptococci (excluding enterococci, e.g., *Strep. faecalis*), *E. coli, P. mirabilis, Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.

Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.

Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia; a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone; in more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.

Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.

Drug/Laboratory Test Interactions—High concentrations (>100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffé reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxy-corticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST II reagent tablets.

Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.

Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers—Excreted in human milk: Exercise caution.

Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.

Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension. *Gastrointestinal*—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.

Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.

How Supplied: Sterile cefoxitin sodium in vials and infusion bottles containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles, and in ADD-Vantage®† vials containing 1 gram or 2 grams cefoxitin equivalent.

New 8th Edition! OBSTETRICS AND GYNECOLOGY

Edited by J. Robert Willson, M.D. and Elsie Reid Carrington, M.D.; Associate Editors Russell K. Laros, Jr., M.D.; William J. Ledger, M.D.; and John H. Mattox, M.D.; with 4 contributors.

In a review of the 7th edition, JAMA said that it "maintains excellence especially in general obstetrics" and "fulfills its purpose as a useful text for various levels of students of obstetrics and gynecology." This new edition, with the addition of two new editors, continues the tradition! Emphasis is on treatment of the "total woman," following the normal life-cycle—birth through pregnancy.

- easy-to-read format facilitates Board review
- a new chapter on androgen disorders
- infertility, endocrinology and endometriosis
- ectopic pregnancy, abortion and infectious disease
- radiologic studies in pregnant women

April, 1987. Approx. 768 pages, 562 illustrations. (Book Code: 05650) About $44.95 (U.S.); $62.25 (Can.)

ESTRADERM®

estradiol transdermal system

Continuous delivery for twice-weekly application.
BRIEF SUMMARY OF PRESCRIBING INFORMATION.
PLEASE SEE FULL PRESCRIBING INFORMATION.

ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than 1 year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer-reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.

The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5-13.9 times greater than in nonusers. The risk appears to depend both on duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen.

Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy.

There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that women who had been exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than four per 1000 exposures. Furthermore, a high percentage of such exposed women (30-90%) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data on the use of other estrogens are not available, it cannot be presumed they would not induce similar changes.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb-reduction defects. One case control study estimated a 4.7-fold increased risk of limb-reduction defects in infants who had been exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one per 1000.

In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses.

If Estraderm is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus and of the advisability of continuation of the pregnancy.

INDICATIONS AND USAGE

Estraderm is indicated for the treatment of the following: moderate-to-severe vasomotor symptoms associated with menopause; female hypogonadism; female castration; primary ovarian failure; and atrophic conditions caused by deficient endogenous estrogen production, such as atrophic vaginitis and kraurosis vulvae.

Studies of the addition of a progestin for seven or more days of a cycle of estrogen administration have reported a lowered incidence of endometrial hyperplasia. Morphological and biochemical studies of endometrium suggest that 12 to 13 days of progestin are needed to provide maximal maturation of the endometrium and to eliminate any hyperplastic changes. Whether this will provide protection from endometrial carcinoma has not been clearly established. There are possible additional risks that may be associated with the inclusion of progestin in estrogen replacement regimens. The potential risks include adverse effects on carbohydrate and lipid metabolism. The choice of progestin and dosage may be important in minimizing these adverse effects.

CONTRAINDICATIONS

Estrogens should not be used in women or men with any of the following conditions:

1. known or suspected cancer of the breast;
2. known or suspected estrogen-dependent neoplasia;
3. known or suspected pregnancy (see Boxed Warning);
4. undiagnosed abnormal genital bleeding;
5. active thrombophlebitis or thromboembolic disorders;
6. history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use.

WARNINGS

1. Induction of Malignant Neoplasms. Long-term continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. There are now reports that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning.)

At the present time, there is no satisfactory evidence that estrogens given to postmenopausal women increase the risk of breast cancer, although a recent long-term follow-up of a single physician's practice has raised this possibility. Because of the animal data, there is a need for caution in prescribing estrogens for women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms.

2. Gallbladder Disease. A recent study has reported a two- to threefold increase in the risk of surgically confirmed gallbladder disease in postmenopausal women receiving oral estrogens, similar to the twofold increase previously noted in users of oral contraceptives.

3. Effects Similar to Those Caused by Estrogen-Progestogen Oral Contraceptives. There are several serious adverse effects of oral contraceptives and other high-dose oral estrogen treatments, most of which have not, up to now, been documented as consequences of postmenopausal estrogen replacement therapy. This may reflect the comparatively low doses of estrogen used in postmenopausal women.

a. Thromboembolic Disease. It is now well established that users of oral contraceptives have an increased risk of various thromboembolic and thrombotic vascular diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. There is evidence that the risk of several of these adverse reactions is related to the dose of the drug. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least four weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization.

While an increased rate of thromboembolic and thrombotic disease in postmenopausal users of estrogens has not been found, this does not rule out the possibility that such an increase may be present or that subgroups of women who have underlying risk factors or who are receiving relatively large doses of estrogens may have increased risk. Therefore, estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders, and they should not be used in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed.

Large doses of estrogen (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown in a large prospective clinical trial in men to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis. When estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptive use should be considered a clear risk.

b. Hepatic Adenoma. Benign hepatic adenomas have been associated with the use of oral contraceptives. Although benign and rare, these tumors may rupture and cause death from intra-abdominal hemorrhage. Such lesions have not yet been reported in association with other estrogen or progestogen preparations, but they should be considered if abdominal pain and tenderness, abdominal mass, or hypovolemic shock occurs in patients receiving estrogen. Hepatocellular carcinoma has also been reported in women taking estrogen-containing oral contraceptives. The causal relationship of this malignancy to these drugs is not known.

c. Elevated Blood Pressure. Women using oral contraceptives sometimes experience increased blood pressure which, in most cases, returns to normal upon discontinuing the drug. There is now a report that this may occur with use of oral estrogens in the menopause and blood pressure should be monitored with estrogen use, especially if high doses are used. Ethinyl estradiol and conjugated estrogens have been shown to increase renin substrate. In contrast to these oral estrogens, transdermally administered estradiol does not affect renin substrate.

d. Glucose Tolerance. A worsening of glucose tolerance has been observed in a significant percentage of patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed while receiving estrogen.

4. Hypercalcemia. Administration of high doses of estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases. If hypercalcemia occurs, use of the drug should be stopped and appropriate measures should be taken to reduce the serum calcium level.

PRECAUTIONS

General

1. A complete medical and family history should be taken before initiation of any estrogen therapy. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, as well as a cervical Papanicolaou test. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed.
2. Because estrogens may cause some degree of fluid retention, careful observation is required when conditions that might be influenced by this factor are present (e.g., asthma, epilepsy, migraine, and cardiac or renal dysfunction).
3. Certain patients may develop undesirable manifestations of excessive estrogenic stimulation, such as uterine bleeding, mastodynia, etc.
4. Prolonged administration of unopposed estrogen therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Estrogens should be used with caution in patients who have or have had endometriosis.
5. Oral contraceptives appear to be associated with an increased incidence of mental depression. Although it is not clear whether this is due to the estrogenic or progestogenic component of the contraceptive, patients with a history of depression should be carefully observed.
6. Preexisting uterine leiomyomata may increase in size during prolonged estrogen use. If this occurs, estrogen therapy should be discontinued while the cause is investigated.
7. In patients with a history of jaundice during pregnancy, there is an increased risk that jaundice will recur with the use of estrogen-containing oral contraceptives. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated.
8. Estrogens may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients.
9. Because the prolonged use of estrogens influences the metabolism of calcium and phosphorus, estrogens should be used with caution in patients with metabolic bone diseases associated with hypercalcemia and in patients with renal insufficiency.

Drug/Laboratory Test Interactions

The results of certain endocrine and liver function tests may be affected by estrogen-containing oral contraceptives. The following changes have been observed with large doses of oral estrogen:

1. increased sulfobromophthalein retention;
2. increased prothrombin time; increased factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability;
3. increased thyroxine-binding globulin (TBG), leading to increased circulating total thyroid hormone (T_4) as measured by column or radioimmunoassay; free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered; TBG was not affected in clinical trials of Estraderm;
4. reduced response to the metyrapone test;
5. reduced serum folate concentration;
6. increased serum triglyceride and phospholipid concentration, and decreased pregnanediol excretion.

The pathologist should be informed that the patient is receiving estrogen therapy when relevant specimens are submitted.

Carcinogenesis, Mutagenesis, Impairment of Fertility

See **WARNINGS** and Boxed Warning.

Long-term continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver.

Pregnancy Category X

See **CONTRAINDICATIONS** and Boxed Warning.

Estrogens should not be used during pregnancy.

Nursing Mothers

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS

See **WARNINGS** and Boxed Warning regarding potential adverse effects on the fetus, induction of malignant neoplasms, increased incidence of gallbladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.

The most commonly reported adverse reaction to Estraderm in clinical trials was redness and irritation at the application site. This occurred in about 17% of the women treated and caused approximately 2% to discontinue therapy.

The following additional adverse reactions have been reported with estrogenic therapy, including oral contraceptives:

Genitourinary System: Breakthrough bleeding, spotting, change in menstrual flow; increase in size of uterine fibromyomata; change in cervical erosion and amount of cervical secretion.

Endocrine: Breast tenderness, breast enlargement.

Gastrointestinal: Nausea, vomiting; abdominal cramps, bloating; cholestatic jaundice have been observed with oral estrogen therapy.

Eyes: Steepening of corneal curvature; intolerance to contact lenses.

Central Nervous System: Headache, migraine, dizziness.

Miscellaneous: Change in weight, edema, change in libido.

Do not store above 86°F (30°C).

Do not store unpouched. Apply immediately upon removal from the protective pouch.

CAUTION: Federal law prohibits dispensing without prescription.

Treatment of menopausal hot flashes with transdermal administration of clonidine

Manubai Nagamani, M.D., Mae Ellen Kelver, M.D., and Edward R. Smith, Ph.D.
Galveston, Texas

A randomized prospective double-blind study was performed to evaluate the efficacy of a transdermal therapeutic system delivering clonidine in the treatment of menopausal hot flashes. Frequency, severity and duration of the flushing attacks before and during the 8-week treatment period were evaluated. The reduction in the number of hot flashes was highly significant in patients receiving the clonidine transdermal therapeutic system. On subjective comparison of flushing attacks before and during treatment, of the 15 patients who received the clonidine transdermal therapeutic system, 80% reported fewer hot flashes; 73% a decrease in severity; and 67% a decrease in duration. Among the 14 patients who were treated with placebo only, 36% reported fewer hot flashes; 29% a decrease in severity; and 21%, shorter duration (frequency, $p < 0.04$; severity, $p < 0.04$; and duration, $p < 0.03$). Reported side effects were minimal, and no significant effect was observed on blood pressure or pulse rate. Transdermal clonidine therapy had no effect on the pulsatile luteinizing hormone secretion. (Am J Obstet Gynecol 1987;156:561-5.)

Key words: Clonidine, transdermal therapy, hot flashes, menopause

Hot flashes are the most annoying symptoms of menopause. They are experienced by 75% to 85% of women going through natural menopause and 37% of premenopausal women undergoing oophorectomy.[1, 2] Estrogen replacement therapy is the most effective form of treatment for relief of menopausal hot flashes. However, when the patient has contraindications to estrogen, alternate forms of therapy become essential. Even though the exact pathophysiologic mechanism of hot flashes is not known, it has been speculated that it is related to catecholamine excess, since similar symptoms are observed in conditions such as pheochromocytoma that are accompanied by catecholamine excess.[3] Casper et al.,[4] however, measured plasma concentrations of catecholamines during episodes of hot flashes and found no such increase and concluded that an excess of central adrenergic activity is probably responsible for the onset of a hot flash. Clonidine, an α-adrenergic agonist, when given orally, has been shown to reduce the frequency of hot flashes.[5, 6]

The present study was undertaken to evaluate the effectiveness of clonidine when given by a transdermal therapeutic system in the treatment of menopausal hot flashes.

Material and methods

Thirty women, six who had undergone spontaneous menopause and 24 who had undergone surgical removal of the ovaries, were included in the study. The mean age of the patients was 41 years (range 25 to 58 years). The frequency of hot flash episodes ranged from 10 to 100 per week. All the patients had stopped estrogen or any other treatment for hot flashes at least 30 days before inclusion in the study. Patients with a history of previous treatment with oral clonidine or a history of hepatic, cardiac, or renal disease or skin diseases of any kind were excluded from the study. The study was conducted in a double-blind fashion. The patients were assigned prospectively to receive either the clonidine transdermal therapeutic system (Dixarit-TTS) or placebo. The placebo and clonidine systems were alike in appearance and neither the physician nor the patient knew who was receiving the therapeutic agent. The systems were provided by Boeringer Ingelheim, Ltd., Ridgefield, Connecticut. The transdermal therapeutic system has the appearance of a small (3.5 cm^2) adhesive bandage. It is composed of a four-layer film, 0.2 mm thick, consisting of a backing layer of pigmented polyester film, a drug reservoir of clonidine, a microporous polypropylene membrane that controls the rate of delivery, and a layer of adhesive formulation of clonidine. Before use, a protective peel strip of polyester that covers the adhesive layer is removed. After application of the system to the intact skin, clonidine in the adhesive layer saturates the skin sites below the system. Clonidine from the drug reservoir then begins to flow through the rate-controlling

membrane and the adhesive layer of the system. The agent is absorbed from the devise through the skin, at a rate of 0.1 mg/day, and is designed to maintain steady-state plasma levels of clonidine for 7 days.

The systems were applied to the upper outer arm and were changed once a week. The patients participated in the study for 10 weeks, 2 weeks without treatment to obtain baseline values and 8 weeks with treatment. Each patient kept a diary and recorded the occurrence of hot flashes and the side effects of treatment during the treatment period. During their visits and at the end of the study, the patients were questioned about the frequency, severity, and duration of hot flashes. Evaluation by the patients of the severity and duration of hot flashes during treatment was purely subjective and no method of quantification was used. The patients were seen at weekly intervals and the blood pressure and pulse rate were recorded at each visit. The transdermal therapeutic system was also changed at these visits.

Fifteen patients received the clonidine transdermal therapeutic system and 15, placebo. One of the patients receiving placebo had dropped out after 2 weeks of treatment and this patient was excluded from statistical analysis.

Hormone analysis. Two of the patients who completed the study and had complete elimination of hot flashes with clonidine transdermal therapeutic system treatment were subsequently studied with frequent sampling of blood for measurement of luteinizing hormone levels. Samples of blood were obtained at 15-minute intervals during a 6-hour period without treatment when these patients experienced 88 and 76 hot flashes per week, respectively, and 2 weeks after application of the clonidine transdermal therapeutic system when they had no hot flashes. The luteinizing hormone levels were measured by double-antibody radioimmunoassay with the materials supplied by the hormone distribution program of the National Institute of Arthritis, Metabolism, and Digestive Diseases and the results are expressed as milli–International Units, with reference to the second international preparation of human menopausal gonadotropins.

Statistical analysis was done by the χ^2 method. The mean numbers of hot flashes before and during treatment were compared by two-way analysis of variance.

Results

The mean number of hot flashes before and during treatment in patients receiving clonidine and placebo are shown in Table I. Even though there was some decrease in the number of hot flashes in women treated with placebo, the reduction in the number of hot flashes was highly significant in patients receiving clonidine. The number of hot flashes recorded as a baseline before treatment was compared with the number recorded each week during the study. The mean decrease for each week, relative to the baseline, is shown in Fig. 1. On subjective comparison of flushing attacks before and during treatment, 12 of 15 patients (80%) who were receiving the clonidine transdermal therapeutic system reported a reduction in the frequency of hot flashes during treatment while only five of 14 patients (36%) receiving placebo reported a reduction ($p < 0.04$ Table II). Of the 12 patients receiving clonidine who reported a decrease in the number of hot flashes, four

	Placebo							
	Weeks of treatment							
Before treatment	1	2	3	4	5	6	7	8
36	30	28	29	27	25	24	25	20
20	19	18	20	18	18	17	27	18
	NS	NS	NS	NS	0.05	0.05	NS	0.04

were completely without hot flashes at the end of 8 weeks and the other eight had a reduction in the number of hot flashes of ≤60%. Eleven of 15 patients (73%) who were receiving the clonidine transdermal therapeutic system reported a decrease in the severity of hot flashes while only four of 14 patients receiving placebo (29%) reported a decrease ($p < 0.04$). The duration of flushing attacks decreased in 10 of 15 patients who received clonidine (67%) but in only three of 14 patients who received placebo ($p < 0.03$). Side effects were minimal and of the same character for both groups. Transient local skin reactions (erythema and/or itching) were observed in four patients using the clonidine transdermal therapeutic system and three receiving placebo. None of the patients receiving the clonidine transdermal therapeutic system complained of dryness of the mouth or drowsiness, which are the common side effects reported with oral clonidine therapy.[5] There were no significant changes in the blood pressure or pulse rate during the study period.

Even though clonidine abolished the hot flashes, it did not abolish the pulsatile secretion of luteinizing hormone. Luteinizing hormone pulses (increment from nadir to peak of >20%) were present during treatment with the clonidine transdermal therapeutic system and the number of luteinizing hormone pulses observed during the 6-hour period during treatment was about the same as that before treatment (Fig. 2). Coefficient of variation of luteinizing hormone levels during the 6-hour period during treatment with clonidine was similar to that before treatment (14% before and 19% during treatment in Patient No. 1 and 22% before and 23% during treatment in Patient No. 2).

Comment

Clonidine is an imidazoline derivative that has been available in an oral form for treatment of hypertension since 1974. An oral preparation of clonidine has also been used in the treatment of hot flashes.[5,6] The dosage that was used in these studies for the treatment of menopausal flushing is lower than that used for hypertension. In the present study clonidine administered transdermally was effective in reducing the incidence, severity, and duration of hot flashes. Possible advantages of transdermal therapeutic system therapy over the oral treatment includes: (1) its effectiveness for 7 days after application, since once-a-week application is more convenient to the patient, and (2) its reduced drug input into the body.

All previous studies on clonidine for treatment of menopausal hot flashes have been with oral therapy. Clayden et al.,[5] in a multicenter, placebo-controlled, double-blind crossover study, observed that clonidine had a statistically high significant effect in controlling menopausal hot flashes. Edington et al.,[6] in a similar study, reported that clonidine significantly reduced the frequency of hot flashes even though the placebo effect was substantial. In a study restricted to patients who had undergone surgical castration. Ylikorkala[7] determined that clonidine significantly dimished the frequency of hot flashes. Schindler et al.[8] observed a significant decrease in the number of hot flashes with clonidine administered orally at a dosage of 150 μg daily. In contrast to these reports, Salmi and Punnonen[9] reported that the effect of clonidine was not significantly different from that of the placebo. Lack of effectiveness in this study could have been due to a dose of <100 μg used by some of the patients in the study. Bolli and Simpson[10] performed a double-blind study in postmenopausal women who were being treated with clonidine for hypertension and determined that clonidine at a dosage of 150 μg daily significantly reduced the menopausal flushing when compared with placebo, while at a dose of 75 μg daily the effect was not greater than that of placebo. The dosage that was delivered by the clonidine transdermal therapeutic system in our present study was 100 μg daily. The placebo effect that was observed in the present study and the previous studies with oral clonidine therapy indicates that emotional and psychological influences accompany the physiologic changes of menopause.

Hot flashes have been demonstrated to precede pulsatile release of luteinizing hormone from the pituitary.[4] The theoretical basis for the use of clonidine for treatment of hot flashes lies in the assumption that the symptoms are triggered by a hypothalamic mechanism that is involved with the pulsatile release of gonadotropin-releasing hormone.[4] Although the exact mech-

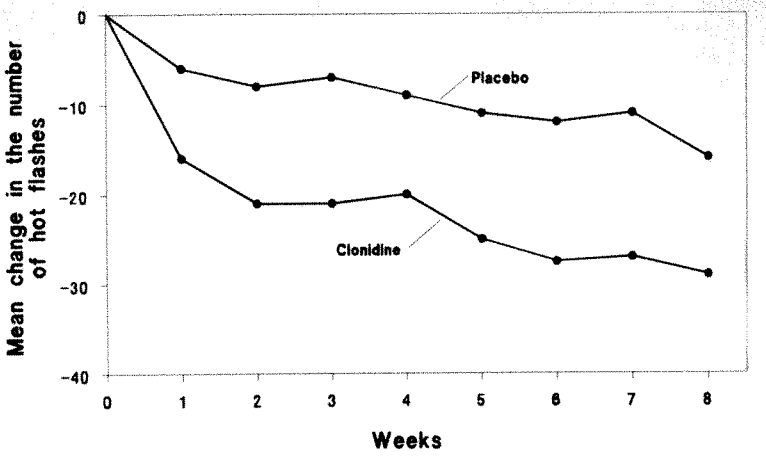

Fig. 1. Mean decrease in the number of hot flashes from initial values.

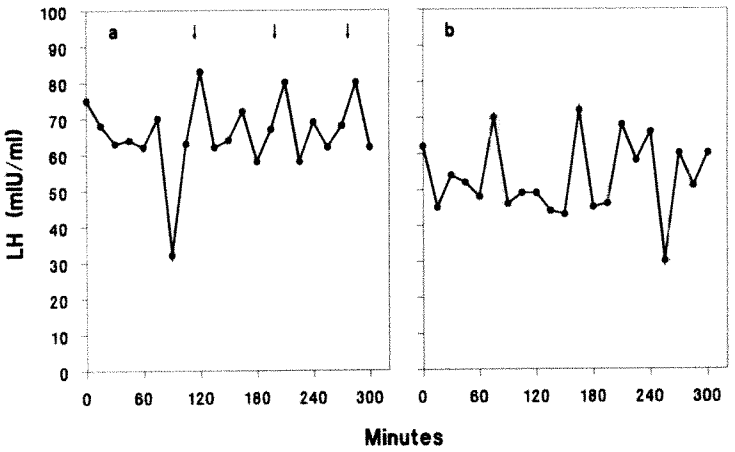

Fig. 2. Serum luteinizing hormone *(LH)* concentrations in a menopausal patient before *(a)* and during *(b)* treatment with the clonidine transdermal therapeutic system. *Arrows* indicate onset of hot flashes.

anism by which clonidine relieves hot flashes is not known, the effect of clonidine on hot flashes appears not to be determined centrally since the hot flashes were eliminated without any change in the pulsatile secretion of luteinizing hormone. Tulandi et al.[11] observed no changes in the number of luteinizing hormone pulses or the total luteinizing hormone secretion after intravenous clonidine administration. Schindler et al.[8] reported no changes in plasma estradiol, luteinizing hormone, follicle-stimulating hormone or prolactin levels in menopausal women receiving oral clonidine for treatment of hot flashes. In earlier studies in animals, clonidine was found to reduce the peripheral vascular responsiveness to vasodilator and vasconstrictor stimuli.[12, 13] Reduction of peripheral vascular reactivity might be one of the mechanisms by which clonidine relieves hot flashes.

In summary, clonidine transdermal therapeutic system therapy would be ideal for symptomatic treatment of hot flashes in postmenopausal women who have contraindications to estrogen replacement therapy. Since the transdermal therapeutic system is effective for 7 days, once-a-week application is more convenient to the patient.

Vaginal birth after two or more previous cesarean sections

George Farmakides, M.D., Roger Duvivier, M.D., Harold Schulman, M.D., Elizabeth Schneider, M.D., and John Biordi, M.D.

Mineola, New York

The recommendation from the American College of Obstetricians and Gynecologists is to allow vaginal delivery after one cesarean section. This report is an update of our experience of 57 women with two or more cesarean sections who were allowed to labor. (Am J Obstet Gynecol 1987;156:565-6.)

Key words: Previous cesarean section, labor, outcome

Recently, the American College of Obstetricians and Gynecologists recommended that women with one previous cesarean section be allowed a trial of labor. One of the exclusions to this recommendation was women with more than one previous cesarean section. Presumably this recommendation was based on the belief that there were not sufficient data to make such a prescription. Unfortunately, there is also no data base to suggest that repeat cesarean section is necessary in these women. This report updates our continuing experience with allowing women to labor after more than one previous cesarean section.

Material and methods

Women in this report were cared for at the Bronx Municipal Hospital of the Albert Einstein College of Medicine and the Winthrop-University Hospital. It has been our policy since 1978 to offer a trial of labor to all women with previous cesarean section unless there was a medical or obstetric complication that contraindicated labor.[1] We considered a vertical uterine incision to be a contraindication. There were 57 women who experienced at least 4 hours of labor (39 with two and 18 with three previous cesarean sections). For evaluation of comparative morbidity we selected 64 women during the same time period who had repeat operations without labor.

Table I. Outcomes in women with more than two previous cesarean sections related to primary indication

Primary indication	*Cesarean section in labor*	*Vaginal delivery*	*Cesarean section without labor*
Dystocia	7	16	40
Malpresentation	1	10	4
Abruptio placentae, toxemia, twins	—	4	3
Fetal distress	2	6	14
Uncertain	3	8	3
Total	13	44	64

In the study group n = 121: no labor, 64; labor, 57; vaginal birth, 44 (77%).

Results

Table I summarizes the outcomes in relationship to the primary indication. Forty-four or 77% of those given a trial of labor were successfully delivered. This finding was not affected by the primary indication for the first cesarean section. There were no differences in neonatal weight among the three groups. There was

From the Departments of Obstetrics and Gynecology, Winthrop-University Hospital.
Received for publication September 3, 1986; accepted September 10, 1986.
Reprint requests: George Farmakides, M.D., 259 First St., Mineola, NY 11501.

no significant perinatal morbidity. Oxytocin was used intravenously in five women, the indications being arrest of labor and premature rupture of the membranes. A uterine scar defect was noted in one woman who was delivered vaginally. There were no observable problems associated with this silent dehiscence. There was no febrile morbidity in the vaginal delivery group. There were three women who became febrile when there was labor with subsequent cesarean section or when cesarean section was done electively. Eighty percent of the women undergoing cesarean section received antibiotics, but none who were delivered vaginally did so. The average length of hospital stay was 3 days for vaginal births and 6 days with cesarean section.

Comment

This report adds modest numbers to those already reported, which seem to indicate that labor is safe after more than one cesarean section. It appears that if there is risk in allowing labor, it must be small or even less than that associated with repeat cesarean section. We hope that others will also give women the opportunity to labor under the safety guidelines recommended by the ACOG so that large enough numbers can be achieved to demonstrate the safety or danger of this approach.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Prospective pricing system by diagnosis-related groups: Comparison of federal diagnosis-related groups with high-risk obstetric care groups

Michael B. Resnick, Ed.D., Mario Ariet, Ph.D., Randolph L. Carter, Ph.D., Andres Cao, M.B.A., Robert R. Furlough, Ph.D., Janet H. Evans, M.S.P.A., Allan G. W. McLeod, M.D., Amelia C. Cruz, M.D., Richard L. Bucciarelli, M.D., John S. Curran, M.D., and William W. Ausbon, M.D.

Gainesville, Tallahassee, Miami, and Tampa, Florida

Of 468 diagnosis-related groups identified by the federal government for Medicaid reimbursement, 15 are related to obstetric hospital care. Each diagnosis-related group is considered a distinct group in which cases are homogeneous with respect to resource consumption. Because the diagnosis-related group system is based primarily on data from community and secondary care hospitals, it does not differentiate sufficiently among high-risk obstetric patients seen at tertiary care institutions, such as Florida's Regional Perinatal Intensive Care Centers. We developed an alternative scheme for diagnosis-related groups, called obstetric care groups, using the federal diagnosis-related groups as the model from which to depart. Data collected for 4192 women during a 2½-year period indicate that obstetric care groups provide more homogeneous groups than diagnosis-related groups for our population of high-risk patients. The obstetric care groups differentiate between no complications, one complication, and two or more complications, while the diagnosis-related groups differentiate only between no complications and one or more complications. Also, complications for obstetric care groups are based on only 19 diagnoses that contribute significantly to resource consumption, while the list of possible complications exceeds 200 for diagnosis-related groups. Although the obstetric care group classification system is simpler than that for diagnosis-related groups, it results in a more accurate reimbursement of hospitalization charges for high-risk obstetric care. (Am J Obstet Gynecol 1987;156:567-73.)

Key words: Prospective pricing system, diagnosis-related groups, Medicaid reimbursement, high-risk obstetric hospitalization

In 1975, a group of investigators at Yale University developed an innovative approach to reimbursement for hospitalization, termed diagnosis-related groups (DRGs).[1, 2] Basically, they proposed a prospective pricing system of hospital charges, rather than the traditional retrospective pricing system in which hospital charges are calculated by totaling daily room charges plus specific goods and services consumed. Later adopted by the State of New Jersey, this prospective pricing system made provision for a fixed amount per discharge, based primarily on the patient's diagnosis, not on the number of days hospitalized and services utilized.[3] Each DRG was considered a distinct group in which cases were homogeneous with respect to resource consumption.[4, 5]

At the federal level, the Health Care Financing Administration adopted DRGs for Medicare reimbursement in 1983, stating that this prospective pricing system would help establish the federal government as a "prudent buyer" of hospital services.[6] Peer review, they maintained, would continue to ensure appropriateness of admissions and discharges and overall quality of care. Under the traditional method of reimbursement, there were few or no restrictions placed on cost of care.[7] In contrast, the new prospective pricing system would reimburse a standard payment for an "average" patient in a given DRG category, regardless of actual costs incurred. The rationale was that all patients within the same DRG classification could be expected to have similar medical requirements; therefore hospital gains and losses would average out, so that in the long run hospital costs would equal reimbursements.[8-10] The DRG

378	Ectopic pregnancy	0.8094	5.5	11	0.088
379	Threatened abortion	0.3169	2.2	8	0.086
380	Abortion without dilatation and curettage	0.2705	1.5	4	0.108
381	Abortion with dilatation and curettage	0.3602	1.4	4	0.154
382	False labor	0.1842	1.2	2	0.092
383	Other antepartum diagnosis with complications	0.4317	3.4	14	0.076
384	Other antepartum diagnosis without complications	0.3245	2.2	9	0.088

*Geometric average length of stay, rather than arithmetic average, was calculated as a more accurate reflection of central tendency.

system was expected to discourage hospitals from lengthening hospital stays unnecessarily and providing goods and services not clearly required.

In Florida, measures for cost containment were taking directions similar to those on the federal level. For example, the Health Care Consumer Protection Act of 1984 placed several constraints on hospitals in an effort to control escalating costs.[11] Proviso language in the 1984 Appropriations Act mandated the development of a prospective pricing system for neonatal intensive care services provided by the 10 Florida Regional Perinatal Intensive Care Centers. These centers give obstetric care to high-risk pregnant women, primarily low-income, and neonatal intensive care to sick or low birth weight infants throughout the state.[12] The federal DRG system did not differentiate enough among expensive neonatal hospitalizations of these infants according to severity of illness, and it did not reimburse adequately. The state needed its own fiscal management tool for determining equitable reimbursement. Children's Medical Services, the state agency that funds the care of this population of infants, requested an analysis of the medical and fiscal data from the records of all neonates cared for in the participating hospitals between July 1, 1980, and June 30, 1985 (8492 infants). As a result of this analysis, a new DRG-type classification system, called neonatal care groups, was developed, providing more equitable reimbursement.[13] This method was implemented July 1, 1985.

A similar type of discrepancy (noted above, between federal DRGs and Florida's experience with neonatal intensive care) was thought to exist between the population sampled to develop the federal obstetric DRGs and our population of high-risk obstetric patients; therefore the current study was undertaken. Furthermore, proviso language in the 1985 Appropriations Act mandated the development of a prospective pricing system for high-risk obstetric care. Hospital charges, diagnoses, procedures, length of hospital stay, and other clinical and fiscal variables had been accumulated for high-risk obstetric patients in the Children's Medical Services statewide data system.[14] These data were used to develop a valid pricing system for high-risk obstetric care.

In this report, we describe the federal DRG system as it applies to obstetric care and the development and applications of Florida's high-risk obstetric care groups (OBCGs).

Federal DRG system

The federal DRG system uses 468 categories, of which 15 pertain to obstetric care (Table I). The major divisions are antepartum, intrapartum, and postpartum hospitalizations. Within the intrapartum type, a further main division is based on whether delivery is cesarean or vaginal. The other major distinctions among groups are whether complications are present and whether operation is performed. Complications are defined as the presence of one or more of a list of more than 200 diagnoses considered in the DRG system to be potentially related to pregnancy.

DRG "weight" is a concept used in the federal system to indicate the intensity and duration of hospital care (and hence the cost) for an average patient in a given group. Weights are based on geometric average charges (a more accurate reflection of central tendency than arithmetic average). The lowest DRG weight is 0.182, for antepartum admission due to false labor (DRG 382).

Table II. Complications that significantly predict hospital charges in high-risk obstetric patients

	Estimated effect	*Frequency of occurrence (%)*	*Partial R^2*	*No. of complications*
Antepartum complication				
Kidney disease	0.51	1.7	0.0076	1
Hyperemesis with ketonuria	0.69	0.8	0.0132	1
Pulmonary dysfunction	0.54	2.3	0.0159	1
Spontaneous premature labor	0.22	25.9	0.0171	1
Viral infection	0.50	1.3	0.0079	1
Amnionitis	0.41	3.0	0.0054	1
Maternal diabetes	0.32	16.7	0.0200	1
Intrapartum complication				
Psychological disorder	0.20	0.8	0.001	1
Hypertension	0.08	7.7	0.001	0
Collagen vascular disease	0.26	0.5	0.0007	1
Amnionitis	0.25	3.0	0.01	1
Arrested progressive labor	0.11	2.7	0.001	0
Polyhydramnios	0.14	1.3	0.0006	0
Premature birth	0.05	23.3	0.007	0
Dilatation and curettage	0.40	1.0	0.0015	1
Endometritis	0.21	2.6	0.003	1
Hemorrhage	0.22	0.9	0.0012	1
Maternal death	1.01	0.2	0.003	2
Tubal ligation	0.25	14.5	0.015	1
Hysterectomy	0.60	0.4	0.005	2
X-ray film obtained	0.15	3.4	0.002	0
Prematurely ruptured membranes	0.11	17.4	0.006	0
Delivery type	0.68	37.1	0.40	—
Maternal diabetes	0.20	16.7	0.014	1
Eclampsia	0.34	0.8	0.0024	1
Fetal monitoring	0.10	72.0	0.004	0
Preeclampsia	0.32	13.2	0.03	1

The lowest intrapartum (delivery) DRG weight is 0.4063, for vaginal delivery without complications (DRG 373). The highest overall DRG weight is 0.9912, for cesarean section with complications (DRG 370). To calculate reimbursement, the DRG weight is multiplied by a "base rate," currently about $3000. For example, reimbursement for a woman having a vaginal delivery with no complications would be: DRG weight × base rate = reimbursement, or 0.4063 × $3000 = $1219. By this method, DRG weights can remain stable, as they are relative and not absolute numbers. The base rate fluctuates with the economy and as a reflection of the current cost of doing business.

"Outlier cutoff" is a concept used to reimburse hospitals for patients with unusually long, expensive hospitalizations.[4] The outlier cutoff is the day of hospitalization considered to lie significantly beyond the geometric average length of stay, for which additional reimbursement is warranted. For example, the geometric average length of stay for a vaginal delivery without complications (DRG 373) is 3.2 days, and the outlier cutoff is 9 days. If an obstetric patient in this DRG is hospitalized more than 9 days, the hospital is reimbursed an additional sum for every outlier day, according to an "outlier weight." At an outlier weight of 0.076 for uncomplicated vaginal delivery, the sum for a woman staying for 12 days would be calculated by the equation: Outlier weight × outlier days × base rate = additional reimbursement, or 0.076 × 3 × $3000 = $684. DRG categories, weights, and outlier cutoff days are shown in Table I.

The federal prospective pricing system with the use of DRGs has been adopted as the basis of Medicaid payment in nine states: New Jersey, Michigan, Ohio, Pennsylvania, Utah, Washington, Minnesota, Oregon, and South Dakota.[13] Blue Cross has implemented DRG-based reimbursements in Arizona, Kansas, Michigan, Nebraska, and Oklahoma.[15, 16]

Obstetric patients and hospital charges in Florida's Regional Perinatal Intensive Care Centers

The records of all sponsored obstetric patients who were hospitalized for obstetric care in Florida's Regional Perinatal Intensive Care Centers between July 1, 1983, and December 31, 1985, were analyzed for fiscal and medical data in a total of 4192 women with hospital charges of $17.47 million. This was possible because demographic, medical, and fiscal data for each mother had been collected, coded, and entered into the data system of the Regional Perinatal Intensive Care Center since 1980.[14] To qualify for participation in the program, each woman had to be classified as "high risk" by her local physician or a screening clinic and referred

Table III. Florida OBCGs

Group No.	*Description*	*OBCG weight**	*Average length of stay† (days)*	*Outlier cutoff day‡*	*Outlier weight*
370.0	Cesarean section, 0 complication	3.0	6.5	10	0.23
370.1	Cesarean section, 1 complication	3.2	7.2	15	0.22
370.2	Cesarean section, ≥2 complications	3.9	8.0	15	0.24
372.0	Vaginal delivery, 0 complication	1.3	3.3	8	0.20
372.1	Vaginal delivery, 1 complication	1.8	4.4	10	0.20
372.2	Vaginal delivery, ≥2 complications	2.2	4.9	10	0.22
376.0	Postpartum	1.5	4.8	15	0.16
383.0	Antepartum, 0 complication	1.3	4.3	10	0.15
383.1	Antepartum, 1 complication	1.7	5.5	15	0.15
383.2	Antepartum, ≥2 complications	2.3	6.9	15	0.17

*Weight reflects both intensity of care and length of hospitalization. Base rate (currently $1000 in Florida) is multiplied by weight to determine total reimbursement for hospitalization. Example: For an uncomplicated vaginal delivery, reimbursement would be: 1.3 × $1000 = $1300.

†Calculated as geometric average length of stay, which reflects central tendency more accurately than arithmetic average.

‡Outlier cutoff day is the day of hospitalization considered to be the limit of a typical hospital stay, beyond which additional reimbursement is allowed. To calculate this additional reimbursement, the base rate of $1000 is multiplied by the appropriate outlier weight, and the result is multiplied by the number of hospitalization days beyond the outlier cutoff day. Example: Reimbursement for a woman hospitalized 18 days for Cesarean section delivery with one complication would be $3200 for the first 15 days (3.2 × $1000) plus 3 days beyond outlier cutoff. Outlier days would be calculated by: days × base rate × outlier weight, or 3 × $1000 × 0.22 = $660. Thus total reimbursement would be $3860.

for tertiary care to one of the 10 Regional Perinatal Intensive Care Centers. She also had to meet the low-income criteria for sponsorship in the program. During the 2½-year study period, 3784 of the 4192 obstetric patients admitted to the program were delivered in a Regional Perinatal Intensive Care Center; the remaining 408 came only for prenatal care and were delivered elsewhere or had a spontaneous abortion.

Hospitalizations and charges were clustered into three main groups: antepartum (predelivery), intrapartum (delivery), and postpartum. If a patient had several antepartum hospitalizations, charges for these hospitalizations were totaled and treated as one hospitalization. Similarly, multiple postpartum hospitalizations were combined.

With the above definitions, the 4192 obstetric patients had 1303 antepartum hospitalizations, 3784 intrapartum hospitalizations, and 88 postpartum hospitalizations. About one third of the women had antepartum hospitalizations. Not many patients had catastrophic charges. Only 23 women had hospital bills exceeding $20,000, and the highest individual charge was $83,000. Of the eight patients who died, five were in the group having charges above $20,000.

Development of Florida's OBCGs

Analysis of the data for the Regional Perinatal Intensive Care Center patients suggested that the federal classifications of antepartum, intrapartum, and postpartum hospitalizations were warranted for our population of high-risk obstetric patients. However, the extensive list of diagnoses used in the federal system to define complications appeared to be unnecessary. Therefore we identified approximately 150 variables contained in the data system of the Regional Perinatal Intensive Care Centers that were judged to have potential for significant fiscal impact. When these variables were analyzed by stepwise regression to determine their effects on hospital charges, 27 emerged as significant (Table II), seven antepartum and 20 intrapartum. Stepwise regression analyses were performed separately for antepartum and intrapartum hospitalizations. Postpartum diagnoses composed only 1.7% of all admissions and were not analyzed by stepwise regression, since this group could have little overall fiscal impact in the program.

Regression analyses demonstrated that delivery type (vaginal or cesarean) was the variable most predictive of hospital charges, accounting for 0.376 of the variance in log charges (out of a total of 0.54 with the use of all variables). Therefore we divided the category "intrapartum" into "vaginal delivery" and "cesarean section." No similar subdivision on the basis of a single predictor variable appeared justified for antepartum and postpartum categories.

The fact that no single variable in any hospitalization category, other than delivery type, was a dominant predictor of hospital charges suggested another approach to defining diagnoses and conditions that would predict charges. "Estimated effects" (coefficients) were calculated for all variables to indicate their individual contributions to charges (Table II). The relative magnitudes of the estimated effects were then averaged for each hospitalization type. Each estimated effect was divided by the average effect for that hospitalization type, and the result was then rounded to the nearest whole

Table IV. Comparison of reimbursements between federal obstetric DRGs and Florida OBCGs

Florida OBCGs			*Comparable federal DRGs*		
OBCG No.	*Description*	*Reimbursement*	*DRG No.*	*Description*	*Reimbursement*
370.0	Cesarean section, 0 complication	$3000	371	Cesearan section, 0 complication	$2261
370.1	Cesarean section, 1 complication	$3200	370	Cesarean section, ≥1 complication	$2973
370.2	Cesarean section, ≥2 complications	$3900			
372.0	Vaginal delivery, 0 complication	$1300	373	Vaginal delivery, 0 complication	$1219
372.1	Vaginal delivery, 1 complication	$1800	372	Vaginal delivery, ≥1 complication	$1660
372.2	Vaginal delivery, ≥2 complications	$2200	374	Vaginal delivery, 0 complication, but sterilization and/or dilatation and curretage	$1648
			375	Vaginal delivery with operation but no sterilization or dilatation and curettage	$2067
376.0	Postpartum (all)	$1500	376	Postpartum, no operation	$1247
			377	Postpartum, operation	$1428
383.0	Antepartum, 0 complication	$1300	384	Antepartum, 0 complication	$974
383.1	Antepartum, 1 complication	$1700	378	Ectopic pregnancy	$2428
			379	Threatened abortion	$951
			380	Abortion without dilatation and curettage	$812
			382	False labor	$553
			383	Antepartum, ≥1 complication	$1295
383.2	Antepartum, ≥2 complications	$2300	383	Antepartum, ≥1 complication	$1295
			381	Abortion with dilatation and curettage	$1081

number. With a few exceptions (Table II), this rounded value was taken as the number of complications for which each diagnosis would count.

With this method, six of seven predelivery diagnoses counted as one complication each; the seventh, hyperemesis with ketonuria, had an estimated effect closer to two complications than one, but because it occurred least frequently of all antepartum complications, it was rounded down to one to simplify computations. On the other hand, the estimated effect of spontaneous premature labor divided by the corresponding average was 0.48 and could have been rounded down to zero but was instead rounded up to one complication because of its high frequency.

Of the 20 intrapartum variables, 11 were rounded to one complication, but one of these, x-ray, was changed to zero to discourage unnecessary use of roentgenograms. The other six zeros were for hypertension, arrested progressive labor, polyhydramnios, premature birth, premature ruptured membranes, and fetal monitoring (Table II). The estimated effects of two intrapartum variables were sufficiently high to warrant identifying them as two complications each: maternal death and hysterectomy.

Our analyses indicated that complications should be used additively to define subgroups but that only three subgroups are required. Thus three of our four main OBCGs (370, 372, and 383) were subdivided into no complications, one complication, and two or more complications (suffixes .0, .1, and .2, respectively). Our prefix numbers were chosen to resemble federal DRG numbers as closely as possible. An example of an OBCG classification would be predelivery hospitalization of a diabetic woman with spontaneous premature labor. Premature labor would count as one complication and maternal diabetes as another, putting the patient in OBCG 383.2: antepartum hospitalization with two or more complications. Details of Florida OBCGs appear in Table III.

The computerized management system for patients served at Florida's 10 Regional Perinatal Intensive Care Centers provides a central data base that stores demographic, clinical, and fiscal data for each patient. The system automatically classifies patients into appropriate OBCG sections and computes entitlements. It identifies outlier days (if any), hospital charges, and hospital entitlement. An interactive report, available on line to each participating center, verifies correct entry of each patient's data into the system. The essentials for determining OBCG reimbursement are shown in Table III. The distribution of 5175 obstetric hospitalizations by OBCG category appears in Fig. 1, along with

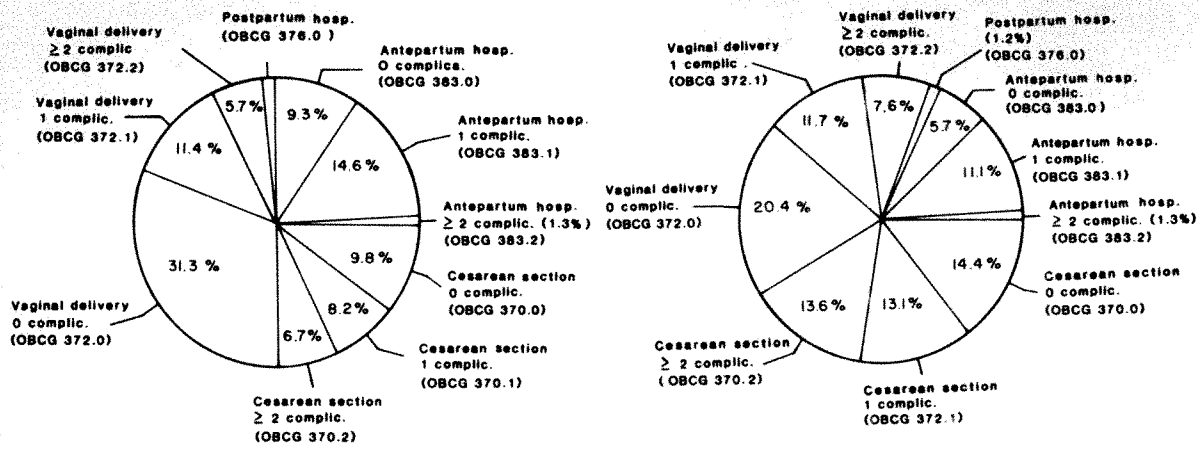

Fig. 1. *Left:* Distribution of 5175 obstetric hospitalizations by Florida OBCG category during the period July 1, 1983, through December 31, 1985. *Right:* Proportion of hospital charges totaling $17.47 million for each Florida OBCG category during the same period.

the proportion of $17.47 million in hospital charges for each category.

Comparison of OBCGs with DRGs

When the federal system of using all variables to define complications for delivery hospitalizations was applied to our data, 40% of the variance in hospital charges could be explained by diagnosis-related groups ($R^2 = 0.4$). When the Florida OBCG system was used, 45.2% of the variance could be explained. This figure is reasonably close to the maximum of 54% that could be obtained with the use of stepwise regression including all of our significant variables (Table II). Thus the simplified OBCG system for delivery hospitalizations predicted log charges more accurately than the corresponding DRG system. Also, the DRG approach uses hundreds of possible diagnoses and conditions to identify "complications," whereas the OBCG system uses only 19 (seven antepartum and 12 intrapartum).

Reimbursements for federal DRGs and Florida's OBCGs are compared in Table IV. Uncomplicated cesarean sections by the OBCG system have charges approximately 25% higher than those of uncomplicated cesarean sections by the DRG system. Cesarean sections with two or more complications in the OBCG system are 30% more expensive than complicated cesarean sections in the DRG system. Also, vaginal deliveries with two or more complications in the OBCG system are reimbursed at a 30% higher rate than complicated vaginal deliveries in the DRG system.

The reimbursement differences between OBCGs and DRGs that occurred in antepartum and postpartum hospitalizations were due to the high-risk nature of the OBCG population compared with the federal population. Moreover OBCGs are based on cumulative antepartum and postpartum time spent in the hospital. Another difference is the method of counting outlier cutoff days; in the OBCG system, outlier cutoff days are counted and reimbursed when all antepartum or intrapartum hospital days added together exceed the outlier cutoff. The OBCG approach of adding length of stays across multiple antepartum (or postpartum) hospitalizations for one patient would tend to discourage long lengths of stay as well as repeated hospitalizations during the same pregnancy.

While outpatient care is not integrated into either the OBCG or the DRG system, it should be noted because outpatient prenatal care is an important component in the treatment of high-risk obstetric patients. The 3784 patients who were delivered in the program had a total of 16,273 outpatient visits and a total of $1.6 million in charges. The average number of prenatal visits was approximately seven for patients who received prenatal care (59% of the total population).

In summary, OBCGs were adopted by Florida's Regional Perinatal Intensive Care Centers program on July 1, 1986. This prospective pricing system has the same advantages as the DRG system over the traditional per diem method as a fiscal management tool. Data collected for 4192 women during a 2½-year period indicate that the system also works better than the federal DRG system for our population of high-risk obstetric patients. The OBCG system results in a manageable number of homogeneous groups that are quickly identified and easy to monitor. The data needed are only whether the hospitalization was for predelivery problems, delivery, or postnatal complications; whether delivery was by cesarean section or vaginal; and whether zero, one, or two complications were present. In addition, only seven antepartum and 12 delivery complications need to be considered, as opposed to hundreds in the DRG system. Although the OBCG in-

trapartum reimbursements for "no complications" and "one complication" are similar to those for the corresponding "uncomplicated" and "complicated" DRG categories, the additional OBCG category for two or more complications provides a significantly higher reimbursement rate for severe problem cases, a distinction that is appropriate for a high-risk obstetric population.

Fetal diaphragmatic hernia: Ultrasound diagnosis and clinical outcome in 19 cases

Beryl R. Benacerraf, M.D., and N. Scott Adzick, M.D.
Boston, Massachusetts

Nineteen cases of congenital diaphragmatic hernia diagnosed in utero are reported with emphasis on sonographic findings, associated congenital and karyotypic abnormalities, the presence or absence of polyhydramnios, and clinical outcome. The survival of these infants was very poor despite accurate prenatal diagnosis, maximal surgical and medical treatment and maximal postnatal care. The overall survival rate was 10.5%, and for fetuses who lived beyond delivery the survival rate was 20%. (Am J Obstet Gynecol 1987;156:573-6.)

Key words: Congenital defects, diaphragmatic hernia, ultrasound

Congenital diaphragmatic hernia is an anatomically simple defect that is easily correctable after birth by removal of the herniated viscera from the chest and repair of the hole in the diaphragm. However, most infants with congenital diaphragmatic hernia die of pulmonary insufficiency, despite immediate operation, because the lungs are too hypoplastic to support extrauterine life.[1, 2] Experimental studies have clearly shown that the pulmonary hypoplasia is a developmental consequence of fetal lung compression by the herniated viscera.[3] Prenatal detection and serial sonographic study of fetuses with congenital diaphragmatic

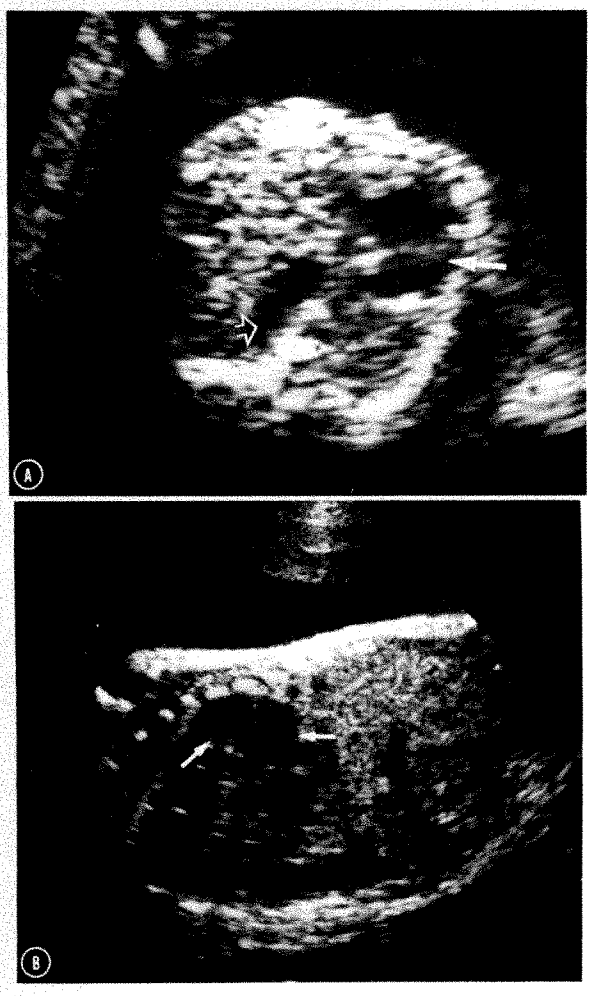

Fig. 1. *A*, Transverse view through the fetal chest at 18 weeks showing the heart deviated toward the right side *(solid arrow)* and the fetal stomach in the left side of the chest as shown by the *open arrow*. Incidental note is made that the heart had only two chambers, a double-outlet right ventricle with aortic atresia. *B*, Longitudinal view of a 32-week fetus showing the heart deviated against the chest wall *(arrows)*, with a large number of echo-poor bowel loops adjacent to the heart in the chest. The liver is noted in the abdomen below the heart.

hernia now make it possible to define the natural history of this lesion and determine the pathophysiologic features that affect clinical outcome.

We report 19 cases of congenital diaphragmatic hernia diagnosed in utero and describe the sonographic findings, associated congenital and karyotypic abnormalities, presence or absence of polyhydramnios, and clinical outcome. Our cases were diagnosed by a single ultrasonographer with postnatal treatment by the same surgical team. The survival of these infants was extremely poor despite early sonographic diagnosis, maternal transport, planned delivery, immediate resuscitation and operation, and maximal postnatal care, including the use of a newly developed extracorporeal membrane oxygenator.

Trisomy 21	1	30
Tetraploidy 21	1	16

Material and methods

Over the course of 3½ years, 19 consecutive cases of congenital diaphragmatic hernia were diagnosed in a laboratory dedicated to high-risk obstetric sonography where more than 20,000 fetuses were scanned. The scans were performed with an Acuson 128, a variable focus phased-array system, and an ATL 300 IC, with 3.5 and 3 MHz transducers, respectively. The diagnosis of congenital diaphragmatic hernia was made when observation was made of an intrathoracic mass having the appearance of liver, bowel, or stomach, with displacement of the heart and mediastinum to the opposite side and with a paucity of abdominal contents in the abdomen (Fig. 1). Other features that were evaluated included amniotic fluid volume, evidence of other congenital malformations, karyotyping when amniocentesis was performed, and clinical outcome. All deliveries were performed at Brigham and Women's Hospital with planned neonatal resuscitation in the delivery room and immediate repair of congenital diaphragmatic hernia at the adjacent Children's Hospital.

Results

The sonographic diagnosis of congenital diaphragmatic hernia was made from 15 to 41 weeks' gestation, with seven being diagnosed between 15 and 21 weeks (Fig. 2). There were 14 fetuses with a left diaphragmatic hernia and five with a right diaphragmatic hernia.

Amniocentesis yielded four abnormal karyotypes:

Table II. Presence of polyhydramnios

Amount of fluid	*Before 24 wk*	*After 24 wk*
Polyhydramnios	1*	6
Normal fluid volume	4	5

Two cases did not have polyhydramnios in second trimester until 28 weeks. One case did not have fluid volume recorded.
*With anencephaly.

two cases of trisomy 18, diagnosed at 15 and 21 weeks; one case of tetraploidy 21, diagnosed at 16 weeks; and one case of trisomy 21, diagnosed at 30 weeks (Table I). Other congenital anomalies that were noted in nine fetuses included cardiac abnormalities, neural tube defects, omphalocele, hydrops, and multiple defects. There were 10 fetuses who had congenital diaphragmatic hernia as the only sonographic diagnosis (Fig. 3). The sonographic findings were confirmed by autopsy or clinical examination in all of these cases except for one fetus with trisomy 18 by karyotype that was too fragmented for pathologic examination after pregnancy termination.

Of the seven fetuses diagnosed with congenital diaphragmatic hernia before 22 weeks' gestation, none survived. Three had abnormal karyotypes (two with trisomy 18 and one with tetraploidy 21), and one fetus had anencephaly with a large encephalocele. All four of these fetuses were aborted. The remaining three fetuses in this group were carried to term. One fetus had severe spinal defects and was stillborn, and the other two had no other congenital abnormalities visualized on sonogram; one did not survive to leave the delivery room, and the other fetus died shortly after operation.

Polyhydramnios was present in only one fetus diagnosed before 24 weeks' gestation; this fetus had anencephaly, which probably caused the polyhydramnios (Table II). Two fetuses with the diagnosis made before 24 weeks (with no other congenital abnormalities) subsequently developed polyhydramnios between 28 and 30 weeks. Of the fetuses older than 24 weeks at diagnosis, the majority had polyhydramnios (six fetuses), and actually a total of eight had third-trimester polyhydramnios when the two cases that were diagnosed earlier are included. There were five fetuses diagnosed with congenital diaphragmatic hernia after 24 weeks that had normal amniotic fluid volumes.

Despite sophisticated perinatal management, the overall outcome was dismal (Table III). There were three cases of intrauterine fetal death or stillbirth. Two neonates deteriorated so rapidly after birth that surgical repair of the congenital diaphragmatic hernia could not be attempted. A total of eight infants died after operation, and severe pulmonary hypoplasia was

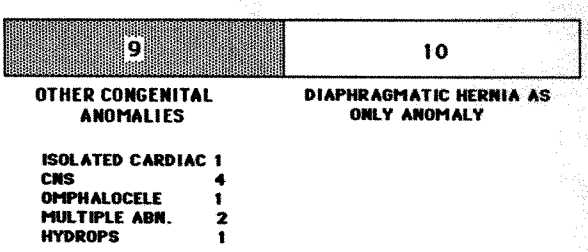

Fig. 3. Presence or absence of associated congenital abnormalities.

Table III. Outcomes

Outcome	*No. of cases*
Induced abortion	4
Intrauterine death	3
Died before operation	2
Died after operation	8*
Survived	2

*Two died before extracorporeal membrane oxygenation could be instituted; four died after a period of extracorporeal membrane oxygenation; two died despite maximal conventional treatment. The longest survival was 5 months.

confirmed at autopsy in each instance. The longest survival was 5 months with chronic respiratory insufficiency as the cause of death. Four of these neonates that underwent operation had the benefit of extracorporeal membrane oxygenation, and two others died before extracorporeal membrane oxygenation could be instituted.

Only two fetuses survived operation, and neither required extracorporeal membrane oxygenation for respiratory support (Table IV). Both cases were diagnosed prenatally during the late third trimester, and one had mild polyhydramnios.

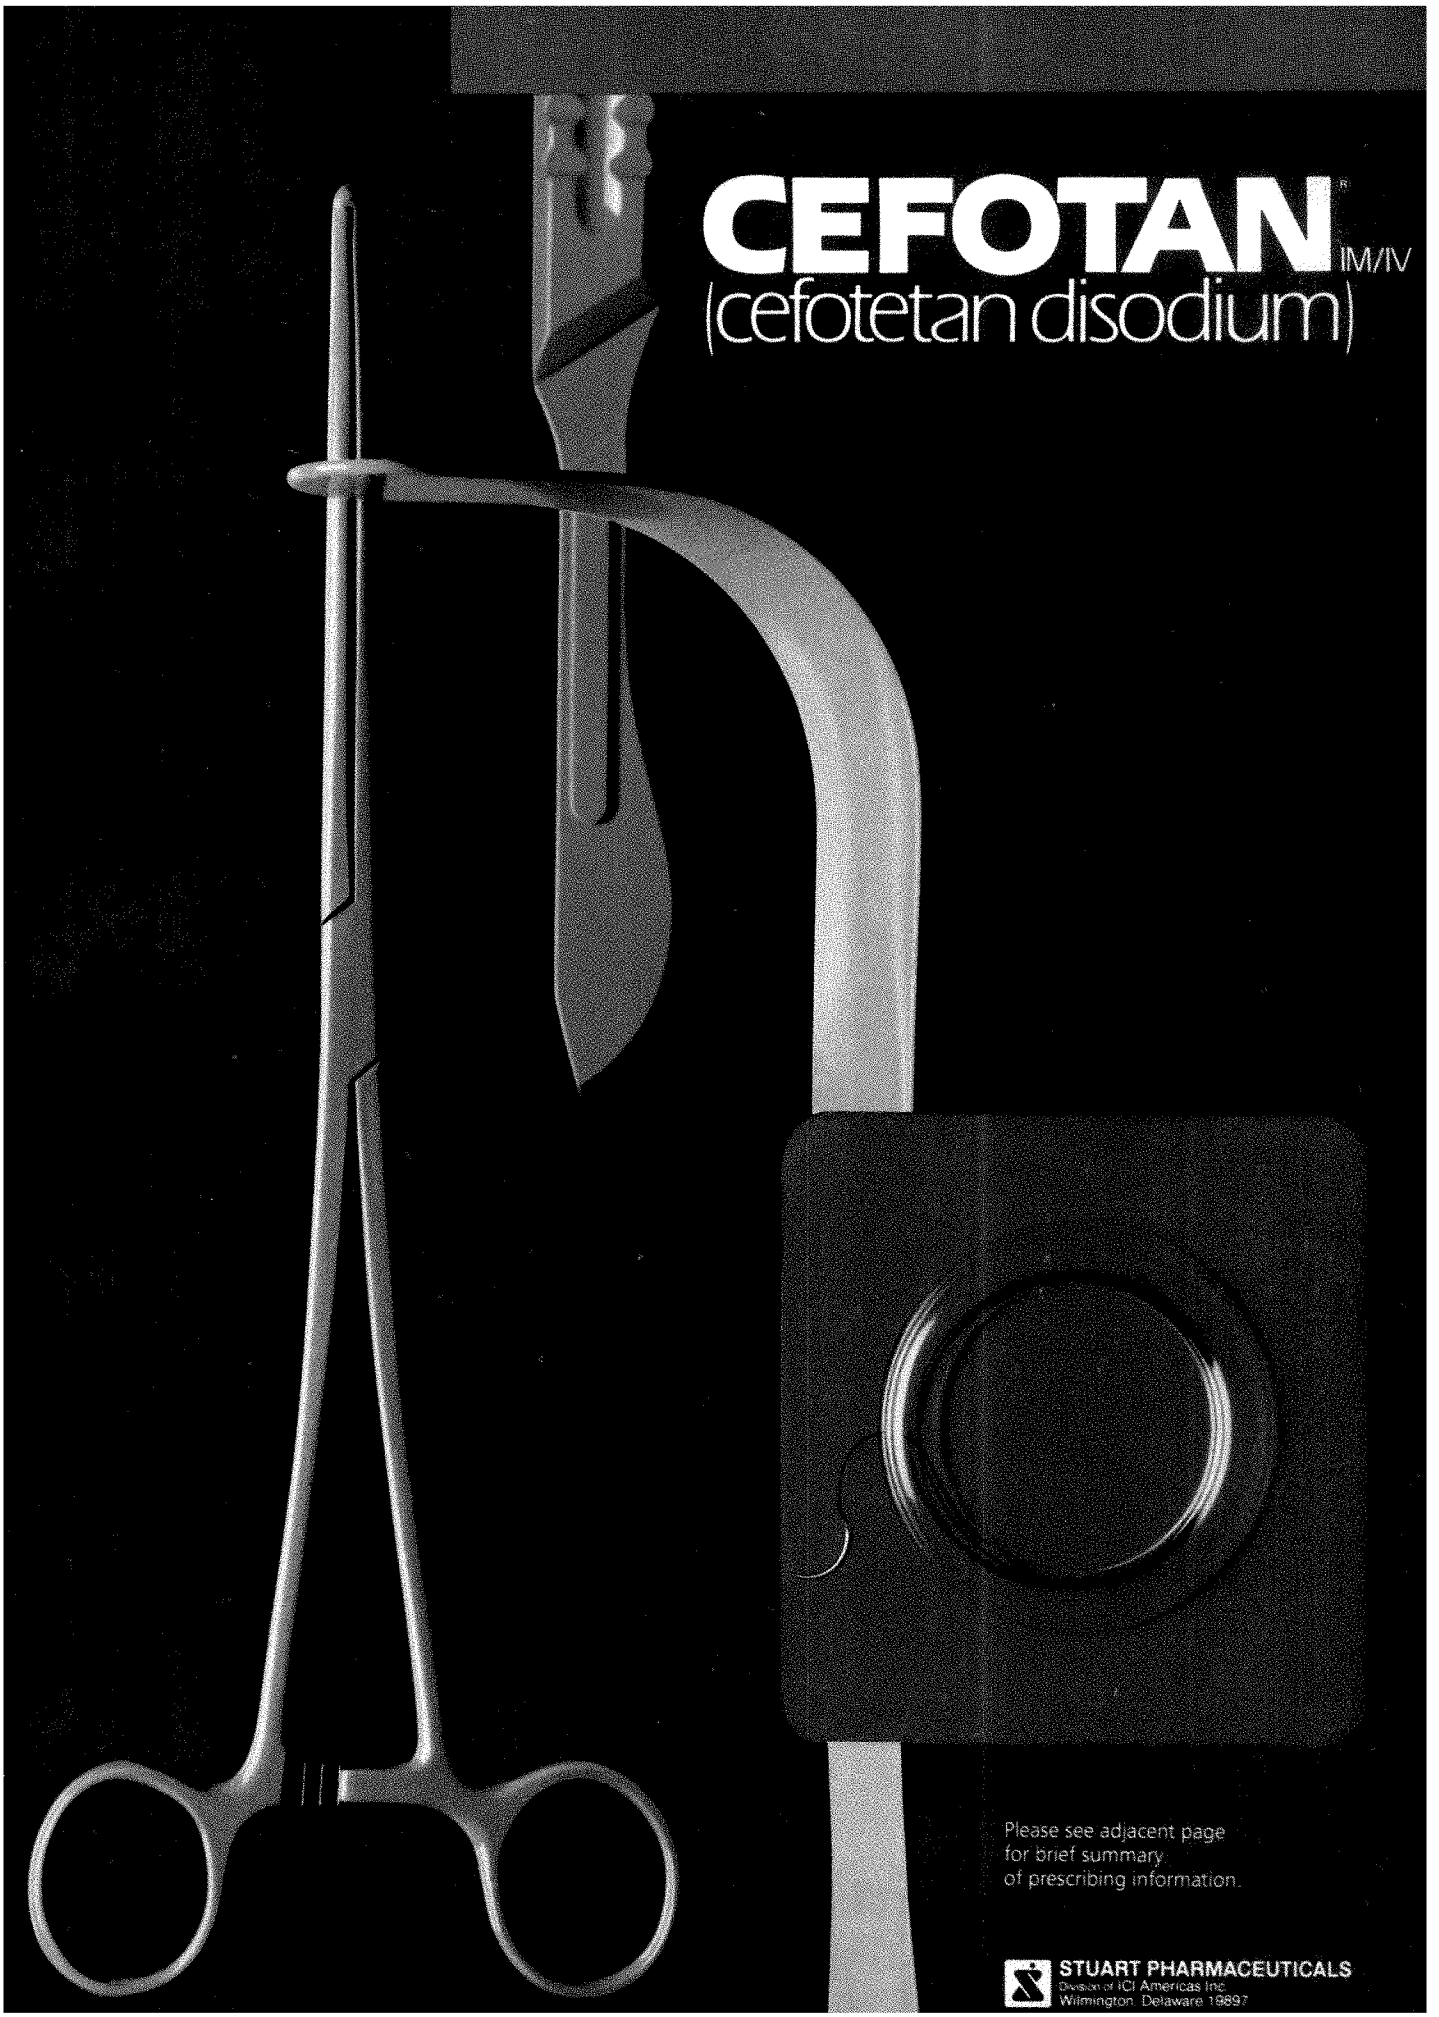
Comment

The prenatal diagnosis of congenital diaphragmatic hernia was made in all 19 cases by identification of herniated abdominal viscera in the fetal chest, abnormal upper abdominal anatomy, and mediastinal shift away from the side of herniation. The diagnosis was made as early as 15 weeks' gestation, with polyhydramnios a common finding after 24 weeks. Since two fetuses with the early gestational diagnosis of congenital diaphragmatic hernia subsequently developed polyhydramnios at the beginning of the third trimester; this suggests that polyhydramnios is a relatively late manifestation of this disease. Consequently, careful examination of the fetal chest is necessary for congenital diaphragmatic hernia to be detected successfully and reliably in the second trimester. Previous work has demonstrated that polyhydramnios not only is a marker for fetal congenital diaphragmatic hernia but also is a good predictor for severe cases with poor prognosis.[4] Al-

Table IV. Survivors

Age at diagnosis	*Hernia side*	*Other abnormality*	*Polyhydramnios*	*Outcome*
37	Left	No	Yes (mild)	Did well, extracorporeal membrane oxygenation not needed
32	Left	No	No	Did well, extracorporeal membrane oxygenation not needed

though the cause of polyhydramnios is unclear in congenital diaphragmatic hernia, functional upper gastrointestinal obstruction from the bowel herniation probably plays a role.



Previous reports have noted that the incidence of associated anomalies with congenital diaphragmatic hernia have varied from "rare" to 56%.[5-7] Current prenatal diagnostic techniques can detect these structural defects, and all were accurately diagnosed in our series. It is noteworthy that 4/19 or 21% of these patients had chromosomal abnormalities, suggesting that amniocentesis for karyotyping is indicated when congenital diaphragmatic hernia is diagnosed antenatally.

The prenatal diagnosis of congenital diaphragmatic hernia has been reported in several case studies and small series.[8-11] The largest series is a multicenter survey of 94 cases, in which 90% of the cases had optimal perinatal care with maternal transport, planned delivery, and immediate resuscitation.[4] Despite sophisticated postnatal therapy, only 20% of these babies survived. Our study describes a series of patients in which the diagnosis of congenital diaphragmatic hernia was made by a single ultrasonographer and where each fetus coming to delivery had maximal resuscitation and immediate operation by the same surgical team. In addition, the membrane oxygenator was available for 1 to 2 weeks of complete postoperative respiratory support for neonates with failure of conventional ventilatory management. Despite these considerations, the overall survival rate was 10.5% (2/19); for fetuses that lived beyond delivery, the survival rate was 20% (2/10).

In the future, prenatal diagnosis may permit surgical intervention before birth. A crucial part of fetal lung development occurs in the middle of the second trimester.[12] If the diagnosis of congenital diaphragmatic hernia is made early, it may be possible to intervene in the second trimester rather than waiting until birth where, despite maximal treatment, survival has not improved. Harrison et al.[13] and Adzick et al.[14] have described the surgical reduction of congenital diaphragmatic hernia in utero in a fetal lamb model, permitting lung development to take place during the remainder of pregnancy with survival at birth. In addition, they have demonstrated the safety of hysterotomy and the control of preterm labor in the nonhuman primate.[15, 16] If this approach is contemplated, early and accurate diagnosis of fetal congenital diaphragmatic hernia is essential even before the onset of polyhydramnios. This approach would require amniocentesis to exclude chromosomal abnormalities as well as careful fetal sonography to detect other structural abnormalities. For the present, the poor prognosis of fetal congenital diaphragmatic hernia requires objective counseling of the parents, particularly when options for pregnancy termination are available.

In intra-abdominal and gynecologic infection due to indicated organisms

Switch to

CEFOTAN® IM/IV
(cefotetan disodium)

The cost-effective replacement for cefoxitin

For Intravenous or Intramuscular Use

BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:

Urinary tract infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris*, *Providencia rettgeri*, and *Morganella morganii*).

Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.

Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.

Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis*,* *Streptococcus* species (excluding enterococci), *E coli*, *Proteus mirabilis*, *Neisseria gonorrhoeae*, *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).

Intra-abdominal infections caused by *E coli*, *Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis*, *B ovatus*, *B thetaiotaomicron*).

Bone and joint infections caused by *Staphylococcus aureus* †

***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.

†Efficacy for this organism in this organ system was studied in fewer than ten infections.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies the following adverse effects were considered related to CEFOTAN therapy.

Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).

Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).

Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).

Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).

Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.
1 g in 10 mL vial (NDC 0038-0376-10)
2 g in 20 mL vial (NDC 0038-0377-20)
1 g in 100 mL vial (NDC 0038-0376-11)
2 g in 100 mL vial (NDC 0038-0377-21)

POSITION AVAILABLE

A full-time position in the area of Reproductive Biology/Endocrinology is available in the Department of OB/GYN, U.C. Davis Medical Center, Sacramento, California. Applicants should be board eligible or certified in Obstetrics and Gynecology and preferably completed subspecialty training in Reproductive Endocrinology. Applicants must demonstrate skill and competence in microsurgery and be knowledgeable in the area of in vitro fertilization.

Responsibilities include patient case management, participation in teaching activities, development and/or participation in research activities and involvement in University and Hospital committees.

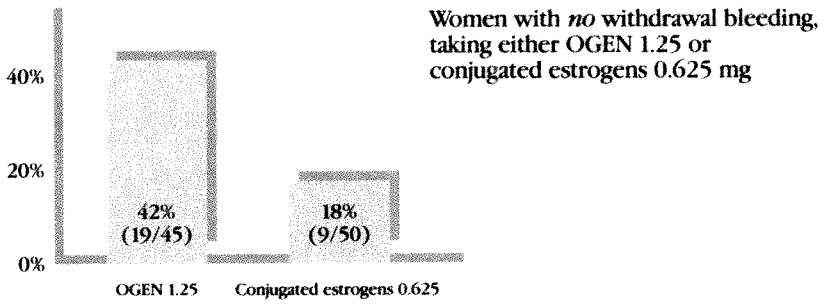
Send curriculum vitae and five references to:

Edward J. Quilligan, M.D.
Chairman, Department of Obstetrics and Gynecology
University of California, Davis, Medical Center
1621 Alhambra Boulevard, Suite 2500
Sacramento, California 95816

The final date for receipt of applications is "Open until filled, but not later than May 1, 1987."

The University of California is an Affirmative Action/ Equal Opportunity Employer.

Position:	Professor and Head Department of Obstetrics and Gynecology
Responsibilities To Be Fulfilled:	Direct the education, research and service programs of an Obstetrics and Gynecology Department in the College of Medicine.
Qualifications Desired:	M.D. degree, board certification or equivalent and demonstrated clinician, scholar and leader in Obstetrics and Gynecology.
Salary:	Appropriate for qualifications and responsibilities for a Professor and Head of Obstetrics and Gynecology. Excellent fringe benefits.
Employer:	The University of Iowa, Iowa City, Iowa 52242 is an Affirmative Action/ Equal Opportunity Employer. Women and minorities are encouraged to apply.
Application:	Interested persons are invited to direct inquiries and submit vitae to: Dr. John Tinker, Professor and Head Department of Anesthesia College of Medicine SE618 University Hospital The University of Iowa Iowa City, Iowa 52242



Withdrawal Bleeding in the ERT Patient:

Necessity or Nuisance?

▣ **To protect against the endometrial hyperplasia** that may result from continuous, unopposed estrogen administration, cyclical estrogen/progestogen therapy is often given.[1] But this may induce withdrawal bleeding, unacceptable to many patients.

▣ **Progestogen initiates bleeding** only when the endometrial mucosa is stimulated to the threshold level by the estrogen.

▣ **Less withdrawal bleeding was experienced** by patients given estrone plus a progestogen than by those given conjugated estrogens plus a progestogen.[2,3] Studies suggest that at doses that control symptoms, estrone alone is less uterotrophic than conjugated estrogens.

Patients received either OGEN or conjugated estrogens 24 days out of 30 for three months. A progestogen, levonorgestrel 0.03 mg, was added from the 15th to the 24th days. Adapted from Wren et al.[2]

▣ **OGEN® (estropipate) may produce less withdrawal bleeding** *at doses that effectively protect them from the symptoms of menopause.*

WARNING:

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade.

The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen.

Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy.

There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. OGEN SHOULD NOT BE USED DURING PREGNANCY.

According to some investigators, the use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. Studies have reported that females exposed in utero to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. In one of these studies, this risk was estimated as not greater than 4 per 1000 exposures. Furthermore, there are reports that a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these reported changes are histologically benign, the investigators have not determined whether they are precursors of adenocarcinoma.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies in the offspring, including heart defects and limb reduction defects. One case control study estimated a 4.7 fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000.

In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. OGEN has not been studied for these uses, and therefore should not be used during pregnancy. There is no evidence from well controlled studies that progestogens are effective for these uses.

If OGEN (estropipate tablets) is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the question of continuation of the pregnancy should be addressed.

INDICATIONS AND USAGE

The cyclic administration of OGEN (estropipate tablets) is indicated for the treatment of estrogen deficiency associated with (See "DOSAGE AND ADMINISTRATION" section):

1. Moderate to severe *vasomotor* symptoms of menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause, and they should not be used to treat these conditions.)
2. Atrophic vaginitis.
3. Kraurosis vulvae.
4. Female hypogonadism.
5. Female castration.
6. Primary ovarian failure.

OGEN (ESTROPIPATE TABLETS) HAS NOT BEEN TESTED FOR EFFICACY FOR ANY PURPOSE DURING PREGNANCY. SINCE ITS EFFECT UPON THE FETUS IS UNKNOWN, IT CANNOT BE RECOMMENDED FOR ANY CONDITION DURING PREGNANCY (SEE BOXED WARNING).

CONTRAINDICATIONS

OGEN should not be used in women with any of the following conditions:

1. Known or suspected cancer of the breast.
2. Known or suspected estrogen-dependent neoplasia.
3. OGEN may cause fetal harm when administered to a pregnant woman. OGEN is contraindicated in women who are or may become pregnant (See Boxed Warning).
4. Undiagnosed abnormal genital bleeding.
5. Active thrombophlebitis or thromboembolic disorders.
6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use.

WARNINGS

1. *Induction of malignant neoplasms.* Long-term continuous administration of natural and synthetic estrogens in certain animal species has been reported by some investigators to increase the frequency of carcinomas of the breast, cervix, vagina, and liver. There is now evidence that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning).

At the present time there is no conclusive evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast. There are, however, a few retrospective studies which suggest a small but statistically significant increase in the risk factor for breast cancer among these women. Therefore, caution should be exercised when administering estrogens to women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms. Careful breast examinations should be performed periodically.

2. *Gall bladder disease.* A recent study has reported a 2 to 3-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens, similar to the 2-fold increase previously noted in users of oral contraceptives. In the case of oral contraceptives, the increased risk appeared after two years of use.

3. *Effects similar to those caused by estrogen-progestogen oral contraceptives.* There are several serious adverse effects of oral contraceptives, most of which have not, up to now, been documented as consequences of postmenopausal estrogen therapy. This may reflect the comparatively low doses of estrogen used in postmenopausal women. It would be expected that the larger doses of estrogen used to treat postpartum breast engorgement would be more likely to result in these adverse effects, and, in fact, it has been shown that there is an increased risk of thrombosis in women receiving estrogens for postpartum breast engorgement.

a. *Thromboembolic disease.* It is now well established that users of oral contraceptives have an increased risk of various thromboembolic and thrombotic vascular diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. There is evidence that the risk of several of these adverse reactions is related to the dose of the drug. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism; it should also be discontinued during periods of prolonged immobilization.

While an increased rate of thromboembolic and thrombotic disease in postmenopausal users of estrogens has not been found this does not rule out the possibility that such an increase may be present or that subgroups of women who have underlying risk factors or who are receiving relatively large doses of estrogens may have increased risk. Therefore estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders, and they should not be used in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed.

Large doses of estrogen (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown in a large prospective clinical trial in men to increase the risk of nonfatal myocardial infarction, pulmonary embolism and thrombophlebitis. When estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptive use should be considered a clear risk.

b. *Hepatic adenoma.* Benign hepatic adenomas appear to be associated with the use of oral contraceptives. Although benign, and rare, these may rupture and cause death through intraabdominal hemorrhage. Such lesions have not yet been reported in association with other estrogen or progestogen preparations but should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has also been reported in women taking estrogen containing oral contraceptives. The relationship of this malignancy to these drugs is not known at this time.

c. *Elevated blood pressure.* Increased blood pressure is not uncommon in women using oral contraceptives. There is now a report that this may occur with use of estrogens in the menopause and blood pressure should be monitored with estrogen use, especially if high doses are used.

d. *Glucose tolerance.* A worsening of glucose tolerance has been observed in a significant percentage of patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed while receiving estrogen.

4. *Hypercalcemia.* Administration of estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases. If this occurs, the drug should be stopped and appropriate measures taken to reduce the serum calcium level.

PRECAUTIONS

A. General Precautions.

1. A complete medical and family history should be taken prior to the initiation of any estrogen therapy. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolau smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed.

2. Fluid retention — Estrogens may cause some degree of fluid retention. Therefore, patients with conditions such as epilepsy, migraine, and cardiac or renal dysfunction, which might be influenced by this factor, require careful observation.

3. Certain patients may develop undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc.

4. Oral contraceptives appear to be associated with an increased incidence of mental depression. Although it is not clear whether this is due to the estrogenic or progestogenic component of the contraceptive, patients with a history of depression should be carefully observed.

5. Preexisting uterine leiomyomata may increase in size during estrogen use.

6. The pathologist should be advised of the patient's use of estrogen therapy when relevant specimens are submitted.

7. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving estrogen-containing oral contraceptive therapy. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated.

8. Estrogens may be poorly metabolized in patients with impaired liver function and they should be administered with caution in such patients.

9. Because estrogens influence the metabolism of calcium and phosphorus, they should be used with caution in patients with metabolic bone diseases that are associated with hypercalcemia or in patients with renal insufficiency.

B. Information for the Patient. See text of Patient Package Insert which appears after PHYSICIAN REFERENCES.

C. Drug Interactions. The concomitant use of any drugs which can induce hepatic microsomal enzymes with estrogens may produce estrogen levels which are lower than would be expected from the dose of estrogen administered.

The use of *broad spectrum antibiotics* which profoundly effect intestinal flora may influence the absorption of steroidal compounds including the estrogens.

Diabetics receiving *insulin* may have increased insulin requirements when receiving estrogens.

Laboratory Test Interference. Certain endocrine and liver function tests may be affected by estrogen-containing oral contraceptives. The following similar changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered.

d. Abnormal glucose tolerance test results.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

D. Carcinogenesis. Studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods (see Boxed Warning). At the present time there is no conclusive evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast. There are, however, a few retrospective studies which suggest a small but statistically significant increase in the risk factor for breast cancer among these women. (See "WARNINGS" section.)

E. Pregnancy. Pregnancy Category X. See "CONTRAINDICATIONS" section and Boxed Warning.

F. Nursing Mothers. Estrogens have been reported to be excreted in human breast milk. Caution should be exercised when OGEN is administered to a nursing woman.

G. Pediatric Use. Because of the effects of estrogens on epiphyseal closure, they should be used judiciously in young patients in whom bone growth is not complete.

ADVERSE REACTIONS

(See Warnings regarding reports of possible induction of neoplasia, unknown effects upon the fetus, increased incidence of gall bladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.) The following additional adverse reactions in decreasing order of severity within each category have been reported with estrogenic therapy, including oral contraceptives:

1. *Genitourinary system.*
Increase in size of uterine fibromyomata.
Vaginal candidiasis.
Cystitis-like syndrome.
Dysmenorrhea.
Amenorrhea during and after treatment.
Change in cervical eversion and in degree of cervical secretion.
Breakthrough bleeding, spotting, change in menstrual flow.
Premenstrual-like syndrome.
2. *Breast.*
Tenderness, enlargement, secretion.
3. *Gastrointestinal.*
Cholestatic jaundice.
Vomiting, nausea.
Abdominal cramps, bloating.
4. *Skin.*
Hemorrhagic eruption.
Erythema nodosum.
Erythema multiforme.
Hirsutism.
Chloasma or melasma which may persist when drug is discontinued.
Loss of scalp hair.
5. *Eyes.*
Steepening of corneal curvature.
Intolerance to contact lenses.
6. *CNS.*
Chorea.
Mental depression.
Migraine, dizziness, headache.
7. *Miscellaneous.*
Aggravation of porphyria.
Edema.
Reduced carbohydrate tolerance.
Increase or decrease in weight.
Changes in libido.

OVERDOSAGE

Numerous reports of ingestion of large doses of estrogen-containing oral contraceptives by young children indicate that serious ill effects do not occur. Overdosage of estrogen may cause nausea and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION

1. *Given cyclically for short-term use:*

For treatment of moderate to severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (e.g., 3 weeks on and 1 week off).

Attempts to discontinue or taper medication should be made at 3 to 6 month intervals.

Usual dosage ranges:

Vasomotor symptoms —One OGEN .625 (estropipate) Tablet to one OGEN 5 Tablet per day. The lowest dose that will control symptoms should be chosen. If the patient has not menstruated within the last two months or more, cyclic administration is started arbitrarily. If the patient is menstruating, cyclic administration is started on day 5 of bleeding.

Atrophic vaginitis and kraurosis vulvae — One OGEN .625 Tablet to one OGEN 5 Tablet daily, depending upon the tissue response of the individual patient. The lowest dose that will control symptoms should be chosen. Administer cyclically.

2. *Given cyclically:*

Female hypogonadism; female castration; primary ovarian failure.

Usual dosage ranges:

Female hypogonadism — A daily dose of one OGEN 1.25 Tablet to three OGEN 2.5 Tablets may be given for the first three weeks of a theoretical cycle, followed by a rest period of eight to ten days. The lowest dose that will control symptoms should be chosen. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. The number of courses of estrogen therapy necessary to produce bleeding may vary depending on the responsiveness of the endometrium. If satisfactory withdrawal bleeding does not occur, an oral progestogen may be given in addition to estrogen during the third week of the cycle.

Female castration and primary ovarian failure —A daily dose of one OGEN 1.25 Tablet to three OGEN 2.5 Tablets may be given for the first three weeks of a theoretical cycle, followed by a rest period of eight to ten days. Adjust dosage upward or downward according to severity of symptoms and response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Treated patients with an intact uterus should be monitored closely for signs of endometrial cancer and appropriate diagnostic measures should be taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

HOW SUPPLIED

OGEN (estropipate tablets, USP) is supplied as OGEN .625 (0.75 mg estropipate), yellow tablets, **NDC** 0074-3943-04; OGEN 1.25 (1.5 mg estropipate), peach-colored tablets, **NDC** 0074-3946-04; OGEN 2.5 (3 mg estropipate), blue tablets, **NDC** 0074-3951-04; and OGEN 5 (6 mg estropipate), light green tablets, **NDC** 0074-3958-13. Tablets of all four dosage levels are standardized to provide uniform estrone activity and are grooved (Divide-Tab®) to provide dosage flexibility. All tablet sizes of OGEN are available in bottles of 100.

A viable pregnancy in a patient with myositis ossificans progressiva

Yvonne S. Thornton, M.D., Stanley J. Birnbaum, M.D., and Nancy Lebowitz, M.D.
New York, New York

Myositis ossificans progressiva is a rare autosomal dominant disorder characterized by a progressive ectopic ossification of the connective tissue of the voluntary muscles and ligaments with associated debilitation and characteristic skeletal malformations. There have been less than 600 cases in the literature. This is the first reported case of a viable pregnancy in a patient with myositis ossificans progressiva. (Am J Obstet Gynecol 1987;156:577-8.)

Key words: Myositis ossificans progressiva and pregnancy, fibrodysplasia ossificans progressiva and pregnancy, pregnancy

Myositis ossificans progressiva, also known as fibrodysplasia ossificans progressiva, is usually manifested before the age of 20 in 98% of patients. The clinical features include microdactyly, reduction defects of all digits, deafness, baldness of the scalp, and mental retardation. The term myositis is misleading, since most of the pathologic features suggest primary involvement of the connective tissue and the muscles are not inflamed. The major defect is dysplasia of fibrous and connective tissue. The initial manifestation closely resembles that produced by inflammation of the muscles, being red, swollen, and painful. The progressive nature of this debilitating disease soon demonstrates fixation of one or both hips, usually during adolescence.

Life expectancy is thought to be shortened in the patient with myositis ossificans progressiva. Patients usually die of respiratory infections and pneumonia due to the general immobility and complete fixity of the chest. This is the first reported case of a viable pregnancy in a patient with myositis ossificans progressiva.

Case report

A. M., a 27-year-old white, Rh-negative woman, gravida 2, para 0-0-1-0, whose last menstrual period was October 1985, was transferred to our medical center at 26 weeks of gestation with a 10-day history of spontaneous rupture of the membranes. The patient had been diagnosed as having myositis ossificans progressiva since the age of 3 with ankylosis of the spine and temporomandibular joint as well as combined restrictive and obstructive pulmonary disease. The patient was fixed in the fetal position with marked rigidity and had been confined to a wheelchair since 1975, with minimal use of the left lower extremity and the distal upper extremities. The patient had absolute inability to abduct the hips. Conception occurred in the knee-chest position.

Her past obstetric history was significant for a spontaneous abortion at 16 weeks of gestation in 1983, which was uncomplicated and did not require dilatation and curettage.

This pregnancy was uncomplicated until 10 days before her transfer, when she had spontaneous rupture of the membranes. She presented to the referring hospital 2 days after rupture of the membranes. Cultures at that time were positive for group B β-hemolytic streptococci, for which she had received amoxicillin for 7 days.

After administration of dexamethasone, the patient was transferred to our obstetric service for further management of this complicated pregnancy.

Physical examination on admission revealed stable vital signs with a temperature of 36° C. The patient was wheelchair bound with multiple contractures and severe involvement of the elbows and lower extremities. The patient was unable to open the mouth or to flex or extend the neck. The lungs had decreased breath sounds at both bases. The fetal heart rate was 130 bpm. Anesthesia, rheumatology, pulmonary disease, and otorhinolaryngology consults were obtained. The patient had widespread multiple areas of heterotopic bone formation with ankylosis of the temporomandibular joint and entire spine, from the cervical to the sacral region, secondary to ossification. Ultrasound examination at the time of transfer to our hospital revealed a biparietal diameter consistent with 26.4 weeks' gestation. The estimated fetal weight was 770 gm with decreased amniotic fluid.

The major concern about this patient was the mode of delivery and the anesthesia required to effect the delivery. Vaginal delivery was impossible because of the total inability of the patient to abduct the hips. Regional

block was impossible because of the ankylosis of the entire spine. Oral intubation was not feasible because of the temporomandibular joint ankylosis. Fiberoptic guided nasal intubation with a bronchoscope was a possibility but there was a significant risk of bleeding and/or trauma with subsequent airway occlusion. Tracheostomy was not considered because of possible ossification of the trachea, which would jeopardize the airway in the future. Therefore local anesthesia was the only safe alternative for this patient.

During her hospitalization, the patient remained afebrile, and the leukocyte count remained within normal limits. Results of a C-reactive protein test were positive, and vaginal cultures were negative for group B β-hemolytic streptococci. The plan of management was conservative. The patient had serial antepartum fetal heart rate tests and ultrasonographic evaluation that revealed appropriate fetal growth with reactive nonstress testing. An elective cesarean section was to be performed when the patient completed 30 weeks of gestation; however, 1 week before that stage of gestation, the patient had a nonreactive nonstress test. A spontaneous contraction stress test was negative and the biophysical profile score was 6. With the possibility of imminent delivery, the patient was given Celestone and continuously monitored. During the continuous monitoring, the fetal heart rate showed several late decelerations and the decision was made to perform a cesarean section for fetal stress.

Local anesthetic was administered, with a dose of 5 to 6 mg/kg of 0.5% to 0.75% lidocaine (5 to 7.5 mg/ml) in order to avoid local anesthetic toxicity. A total of 50 to 60 ml of 0.5% lidocaine infiltrated the skin to the peritoneum and a classical cesarean section was performed with a delivery of a live female infant weighing 1165 gm. Apgar scores were 6 and 9, at 1 and 5 minutes, respectively. The cesarean section proceeded without incident and a bilateral tubal ligation was performed at that time.

The patient's course was benign with good wound healing. She received Rh immune globulin and was discharged in good condition without worsening of pulmonary status. The infant was taken to the neonatal intensive care unit for observation. The 29-week female infant had mild respiratory distress and abnormal posturing and alignment secondary to the decreased intrauterine amniotic fluid. The sepsis evaluation was negative. There were no skeletal abnormalities. The infant continued to thrive and was discharged after 30 days, weighing 1520 gm, to be followed up in the nursery of the referring hospital.

Comment

Myositis ossificans progressiva is an autosomal dominant disorder and it has been suggested that advanced paternal age is the most important factor in the occurrence of new mutations. Contrary to an earlier report of Connor and Evans,[1] patients with myositis ossificans progressiva are fertile and are capable of maintaining a pregnancy.

In this patient with myositis ossificans progressiva, as pregnancy progressed with uterine enlargement, worsening of restrictive pulmonary disease was inevitable. With the complete immobility of the patient, the pregnancy also placed her at a higher risk for thromboembolic disease. Smith[2] reported exacerbation of the myositis ossificans, as well as poor wound healing and ossification of the scar tissue after operation. This was not the case in this patient.

A major concern in this case was the risk of anesthesia. This was minimized by the use of local anesthetic with an emergency support system of fiberoptic nasal intubation.

The management of myositis ossificans progressiva is conservative. Surgical removal of ectopic bone alone is invariably followed by recurrent ossification and should therefore be avoided.

Despite the good outcome in this case, the potential life-threatening risks of pregnancy should be discussed with the patient with myositis ossificans progressiva before conception. Because this is an autosomal dominant disease that carries a 50% risk of transmission to offspring in addition to severe physical limitations that significantly impair the patient's ability to care for her infant, elective sterilization should also be discussed with the patient.

We would like to thank Dr. Hamid Mootabar for referring this most interesting patient to our obstetric service for definitive care and delivery.

Can ultrasonography replace amniocentesis in fetal gender determination during the early second trimester?

E. Albert Reece, M.D., Hung N. Winn, M.D., Macor Wan, M.D., Carol Burdine, R.D.M.S., Jacqueline Green, M.S., R.D.M.S., and John C. Hobbins, M.D.

New Haven, Connecticut

Fetal gender was prospectively determined by ultrasonography in 115 patients with singleton pregnancies between 16 and 20 weeks of gestation. Gender determination was performed as a part of the sonographic examination preceding genetic amniocentesis, and the results were compared to the amniotic fluid fetal karyotype results. Our rate of visualization of the fetal external genitalia was 83.5%. The accuracy rate for gender determination was 90% in male infants and 100% in female infants, with an overall rate of prediction of 92.7%. (Am J Obstet Gynecol 1987;156:579-81.)

Key words: Ultrasound, fetal sex, fetal gender, prenatal diagnosis

Throughout centuries, guessing about the sex of an unborn child has been a popular topic among expectant parents and their families. Until recently, fetal gender determination has been purely speculative. Improved resolution of ultrasound equipment has made it possible to visualize the fetal genitalia. Most studies are done beyond 20 weeks of gestation, when this information is often of sociologic interest only. Few studies have confined themselves to the early second trimester (16 to 20 weeks), when this information may have a medical impact, especially in cases of sex-linked diseases. The purpose of this communication is to report the results of a prospective study between 16 and 20 weeks, in which gender determination was assigned on the basis of sonographic criteria and confirmed by amniotic fluid karyotype results.

Subjects and methods

Our study population consisted of 115 patients with singleton pregnancies who were referred for genetic amniocentesis between 16 and 20 weeks' gestation. Gender determination was performed as a part of the sonographic examination preceding the amniocentesis procedure. The gestational age was based on the last menstrual period and its correlation with various sonographic measurements. The ultrasound machines used in this study were equipped with 3.0 or 3.5 mHz linear-array real-time transducers (Acuson 128, Acuson, Inc., Mountain View, California; General Electric RT 3000 and RT 2600, General Electric Medical Systems Div., Milwaukee, Wisconsin). All scans were obtained by two experienced sonographers. Fetal gender was prospectively assigned on the basis of imaging of the fetal external genitalia. This was accomplished by use of two planes of orientation, longitudinal and transverse views of the fetal pelvis, and with tilting of the transducer at appropriate angles to obtain the best image of the external genitalia. Male gender was assigned when the scrotum and penis were seen (Fig. 1). At this gestational age the testes are undescended and would not be visualized. Gender was designated as female if the labia majora were visualized (Fig. 2). Gender was not assigned when there was uncertainty. The final gender determination was based on the amniotic fluid karyotype results.

From the Section of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology at Yale University School of Medicine.

Received for publication September 12, 1986; accepted September 19, 1986.

Reprint requests: E. Albert Reece, M.D., Yale University School of Medicine, Department of Obstetrics and Gynecology, 333 Cedar St., New Haven, CT 06510.

Results

The results are summarized in Table I. Among 115 fetuses examined, fetal external genitalia were visualized with clarity for gender determination in 96 fetuses (83.5%). In 70 fetuses (60.9%) who were sonographically assigned as male, chromosome analysis confirmed 63 male fetuses (54.8%) and seven female fetuses (6.1%). Thus the true positive rate for male gender was 90%. All 26 fetuses assigned female by sonographic examination were confirmed to be female by chromosomal analysis. The overall accuracy rate for gender determination was 92.7%.

Comment

Knowledge of the fetal gender during the early second trimester is crucial in prenatal diagnosis and management of many medical conditions. In certain X-linked recessive disorders, the only relevant information obtained from a genetic amniocentesis is the fetal sex. This same information can be obtained by ultrasonography with a high degree of accuracy without the risk of pregnancy complications associated with

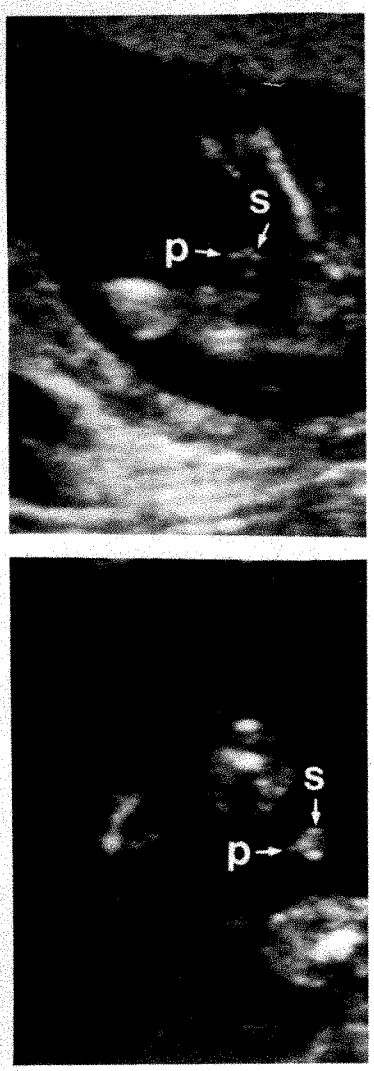

Fig. 1. The male external genitalia with penis *(p)* and scrotum *(s)* are demonstrated in a fetus of 18 weeks' gestation. *Upper panel* represents a cross-sectional view of the fetus at the level of the hip joint. With further tilting of the transducer the penis and scrotum are clearly seen *(lower panel)*.

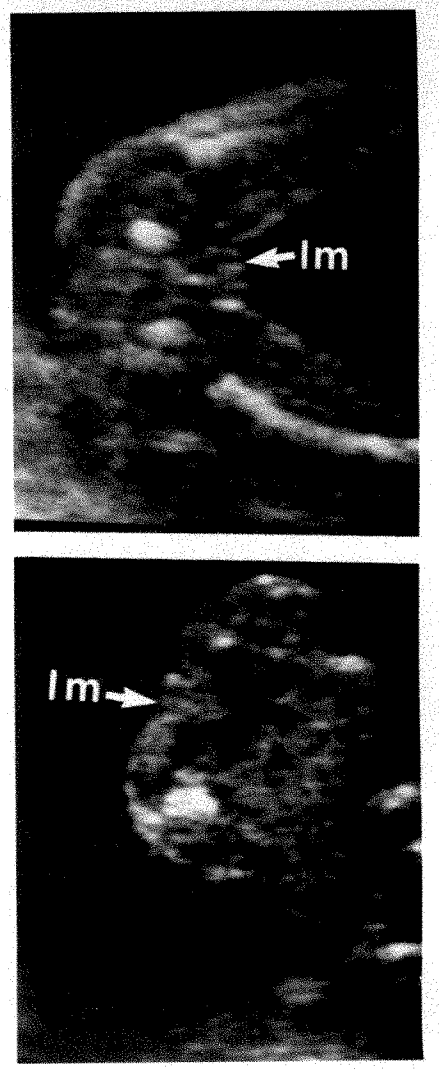

Fig. 2. Ultrasound picture demonstrating the female external genitalia in a fetus at 18 weeks of gestation. Labia majora *(lm)* were seen. *Upper panel* represents a transverse view of the pelvis at the level of the hip joint. *Lower panel* shows labia majora *(lm)* when the transducer was slightly tilted.

Table I. Gender determination in 115 fetuses between 16 and 20 weeks of gestation with the use of ultrasonography

Amniotic fluid karyotype	*Ultrasound gender determination*							
	Male		*Female*		*Not assigned*		*Total*	
	No.	*%*	*No.*	*%*	*No.*	*%*	*No.*	*%*
46,XY	63	54.8	0	—	11	9.6	74	64.4
46,XX	7	6.1	26	22.6	8	6.9	41	35.6
Total	70	60.9	26	22.6	19	16.5	115	100

True positive rates:

$$\text{Male fetuses} = \frac{63}{70} \times 100 = 90\%$$

$$\text{Female fetuses} = \frac{26}{26} \times 100 = 100\%$$

$$\text{Overall} = \frac{89}{115} \times 100 = 92.7\%$$

amniocentesis. Identification of a male fetus would prompt further study. In other sex-limited diseases such as posturethral valve obstruction, identification of a female fetus essentially rules out this disorder as a cause of fetal obstructive uropathy. In twin gestations with fetuses of different gender, ultrasonography can be useful in determining to which fetus a respective chromosome composition belongs.

In the gestational period between 16 and 20 weeks, rates of visualization of the fetal external genitalia have ranged from 15% to 40%, and error rates in those fetuses with sonographically visible external genitalia have ranged from 4% to 12%.[1] We were able to visualize the external fetal genitalia 83.5% of the time with a diagnostic accuracy rate of 92.7%. These results are comparable to those of Natsuyama,[2] in which he reported a 90% accuracy rate and visualization rates of 68% to 97%, depending on fetal position during the period of 15 to 19 weeks of gestation. His technique utilized multiple planes and sections as well as the identification of specific bony landmarks. He indicated that such complicated maneuvers would possibly be best suited for purely scientific interests. Our technique uses simple transverse and longitudinal planes, suited for routine ultrasound.

The results of our study demonstrate that gender determination during the early second trimester with the use of ultrasonography is possible with a high degree of accuracy. This information can be useful in the decision making and subsequent management of certain cases.

Atraumatic removal of secretions from the prepubertal vagina

Susan F. Pokorny, M.D., and Jane Stormer, L.V.N.
Houston, Texas

Adequate vaginal secretions for laboratory tests are difficult to obtain from the prepubertal girl. A simple atraumatic technique for obtaining several milliliters of vaginal secretions is described. This is extremely useful for the clinician evaluating the child with vulvovaginitis and/or possible sexual abuse. (Am J Obstet Gynecol 1987;156:581-2.)

Key words: Vaginal secretions, prepubertal, vulvovaginitis, sexual abuse

Anxiety is common among physicians who need to obtain secretions from the vagina of a prepubertal child. Because children rarely comply with these procedures, there is a chance of iatrogenic damage to the thin, delicate, unestrogenized mucosa of the genital tract. Furthermore, because these procedures can have long-lasting psychosocial effects, manipulation of the genital tract should be performed cautiously.

Techniques described in most textbooks for obtaining vaginal secretions are far from ideal.[1, 2] They can be traumatic and yield only small amounts of material. Q-tips are abrasive to the unestrogenized mucosa and should not be used. Eye droppers, pipettes, and plastic cannulas are smooth and unabrasive but can cause trauma secondary to inadvertent patient movement. Any single-chambered tube or cannula placed in a small vagina will be sucked against the vaginal wall when an effort is made to withdraw secretions, making the yield of material very small. Furthermore, the suction frequently alarms the child.

We have developed a very satisfactory atraumatic method for obtaining adequate vaginal secretions by use of a catheter-within-a-catheter. The outer catheter holds the vaginal wall away from the inner catheter, through which the diluting solution is injected and withdrawn from the vagina. The two catheters are obtained by cutting (with a sterile technique) 4 inches from the distal end of a No. 12 bladder catheter and the proximal (hub end) 4½ inches of an intravenous butterfly catheter. The butterfly tubing is inserted inside the bladder catheter and a small syringe with approximately 1 ml of sterile normal saline solution is attached

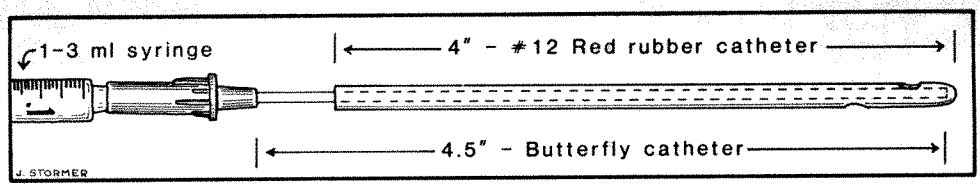

Fig. 1. Assembled catheter-within-a-catheter, as used to obtain samples of vaginal secretions from prepubertal patients.

to the hub of the "butterfly" tubing (Fig. 1). This makes a catheter-within-a-catheter that can be gently inserted into the vagina of the child. Should the child move suddenly, the examiner can brace the insertion hand against the thigh of the child and the catheters remain in place. Although some children report that they "feel" the insertion, once the catheter is in place, none have reported a painful experience.

Once the catheter is inserted, the examiner can alternately inject and aspirate the small amount of diluting fluid a few times to obtain a good admixture of material from the upper vagina and then quickly withdraw the whole apparatus after drawing the material back into the syringe. Depending on the situation, the examiner can obtain from one atraumatic procedure enough fluid for the following: an examination for sperm particles and acid phosphatase, a Gram stain, a gonorrheal culture, a chlamydial culture, a "wet mount," and other cultures as needed.

Many children with vulvovaginitis go through needless courses of creams and antibiotics because the infectious organism is never identified. Many children who have been sexually exploited have their stories unsubstantiated because material for forensic rape kits and/or cultures is never obtained. It is hoped through use of the technique described in this paper that the management of children with these common pediatric gynecology problems will be improved.

Preliminary report on the use of tamoxifen in the treatment of endometriosis

G. M. Haber, M.D., and Y. F. Behelak, Ph.D., M.D.
Montreal, Quebec, Canada

Tamoxifen, an antiestrogen, was used in the treatment of two women with a long-standing history of endometriosis. After a 6-month period of treatment, both patients were symptom free and both showed a marked decrease in the size of their endometriotic lesions. It was significant that ovulation was documented in both patients while receiving the treatment regimen. The use of tamoxifen as an alternative modality in the treatment of endometriosis, especially for women desiring to conceive, is discussed. (Am J Obstet Gynecol 1987;156:582-6.)

Key words: Tamoxifen, endometriosis, treatment

Tamoxifen, as well as other related antiestrogen compounds, seems to have some estrogen-like effects and, like estrogens, underwent translocation from the cytoplasm to the nucleus. However, in contrast to 17β-estradiol, the antiestrogen receptor complex exhibited long-term nuclear retention resulting in early estrogen-like responses but a later manifestation of estrogen antagonism by failing to replenish the cytoplasmic estrogen receptors.

In this preliminary study we report on the use of the antiestrogen tamoxifen in the treatment of two cases of endometriosis which were unresponsive to the usual

therapeutic modalities currently in use such as danazol or the estrogen/progestin combination oral contraceptive.

Case reports

Case 1. This patient came to medical attention when she presented at age 29 with signs and symptoms of an acute abdomen. At laparotomy she was found to have a ruptured endometrial cyst of the right ovary. She had endometrial lesions on the sigmoid colon, with adhesion of the rectosigmoid to the posterior cul-de-sac. The left ovary had a small 2 cm cyst, while both tubes appeared normal.

On discharge from hospital she was to receive 200 mg of danazol three times daily. She continued the administration of danazol for 3 months, after which treatment was switched to an estrogen/progestin combination oral contraceptive, which she received for a period of 6 months.

The patient was next seen 9 months later with a history of reactivation of endometriosis, especially bowel symptoms. She was restarted on a 9-month course of danazol, at the end of which she underwent a diagnostic laparoscopy and laparotomy. Findings at laparotomy showed dense adhesions throughout the pelvis. Bilateral salpingoovarioplasty and lysis of adhesions were carried out, and the patient was observed over a period of 1 year during which time she tried unsuccessfully to conceive. Meanwhile her symptoms worsened rapidly with clinical evidence of significant uterosacral ligament thickening.

In view of the extreme pain she was enduring which was not responsive to analgesics or antiprostaglandins, tamoxifen therapy was suggested to her in lieu of the radical surgical treatment that she was now insistently demanding. She was started on a protocol of 10 mg of tamoxifen (ICI Pharma) twice daily for a clinical trial period of 6 months, to be followed by a diagnostic laparoscopy.

Case 2. This patient was seen at age 24 with a 6-year history of severe dysmenorrhea and irregular intermenstrual bleeding. She had been receiving oral contraceptives intermittently for a period of 8 years. Her physical examination at the time was within normal limits, and the oral contraceptives were continued. Two years later she opted to stop using the oral contraceptives and tried unsuccessfully to conceive in spite of a negative infertility workup. She now complained of increasing pelvic pain, dyspareunia, and dysmenorrhea. Clinical examination revealed prominant nodularity of her uterosacral ligamants.

Laparoscopy revealed scattered endometriotic lesions in the posterior cul-de-sac and on the uterosacral ligaments. The tubes seemed free of lesions but were adherent and showed some degree of obstruction with hydrotubation. The ovaries had several small endometriotic lesions.

The patient was next treated with danazol for a period of 8 months, which was followed by a recurrence of her symptoms after discontinuation of the drug. A second 6-month course of danazol failed to improve her condition, and she still failed to conceive. After discussion with the patient, tamoxifen therapy was suggested, and she agreed to a 6-month trial period to be followed by a laparoscopy.

Serial determinations of serum levels of follicle-stimulating hormone, luteinizing hormone, and progesterone were carried out during the midluteal phase of the patients' menstrual cycles both before and after treatment with tamoxifen. Concurrent with the treatment, the patients were asked to keep a diary, recording any symptoms they incurred during the treatment period. Both patients were seen and examined at 6-week intervals for subjective and objective evaluation of their condition and for documentation of any clinical signs of improvement. Patient A recorded her basal body temperatures throughout the study period. At the end of a 6-month tamoxifen regimen both patients underwent a diagnostic laparoscopy.

Results

The hormonal profile documented over the 6-month study period was as follows: The levels of serum follicle-stimulating hormone, luteinizing hormone, and progesterone were as expected for day 19 of the control or pretreatment cycle. Treatment with tamoxifen did not result in significant changes in the levels of any of the hormones assayed. Progesterone levels at midluteal phase were consistent with ovulation throughout the 6-month treatment period.

Subjectively both patients complained of hot flushes, which were more frequent early in the treatment period. They both also noted increased fatigue and constipation. One of the patients noted an exacerbation of acne. It is significant that they both noted that all of their symptoms were relatively less pronounced than during their treatment with danazol, and neither patient complained of breast tenderness. Menses was normal and no voice change or hair loss was noted. Both were symptom free 6 months after treatment.

Clinical examination of Patient 1 showed no improvement after 6 weeks of treatment with the thickening of the uterosacral ligaments quite prominent and tender. By 12 weeks, however, there was less tenderness and by 6 months there was minimal clinical evidence of cul-de-sac scarring.

Patient 2 showed marked improvement during treatment but the symptoms recurred, albeit to a lesser degree, 3 to 4 months following discontinuation of treatment with tamoxifen.

Laparoscopic examination at the end of the treatment period was very rewarding. We found very little evidence of endometriotic lesions except for an occasional trace of inactive endometriosis.

Neither of the patients became pregnant, although both did document regular ovulation while receiving tamoxifen therapy.

Comment

Antiestrogens are nonsteroidal compounds capable of antagonizing many of the actions of estrogens. In particular, these compounds have been shown to suppress estrogen-stimulated uterine growth in a variety of animal species and to cause the regression of hormone-dependent mammary tumors as well as to inhibit the growth of estrogen receptor containing human breast cancer cells.[1-4] They also tend to alter gonadotrophin secretion patterns in premenopausal women.[5]

The study of these compounds was initially prompted by the search for an effective contraceptive agent; however, they are now viewed with more interest for their capacity to control the growth of hormone-dependent neoplasms, particularly tumors of the breasts and more recently for the induction of ovulation in women with luteal phase deficiency.[6,7]

The hormone responses to short-term administration of tamoxifen for induction of ovulation have been studied by a number of authors.[5,8-11] Groom and Griffiths[11] observed a twofold to eightfold increase in estradiol levels during the test cycles, which was most pronounced at the times of midcycle and midluteal peaks.

The plasma concentrations of luteinizing hormone did not vary from control levels and those reported for normal ovulatory women.[12] There was a slight increase observed in plasma progesterone concentrations after tamoxifen treatment.[11]

Similar results were obtained by Sherman et al.[5] who studied the effects of long-term administration of tamoxifen in premenopausal women. In their report all subjects continued to have regular menses with biphasic basal body temperature records. The mean estradiol concentration at the midcycle peak and during the luteal phase was twice that observed during the nontreatment cycle. They also observed that the concentration and secretory patterns of luteinizing hormone and follicle-stimulating hormone were not greatly changed. The integrated luteal phase progesterone concentrations during tamoxifen cycles were increased over those of control cycles although the secretion pattern observed was similar to that in nontreated women.

In their study of tamoxifen as a treatment for luteal phase deficiency Fukushima et al.[9] found 10 of 12 endometrial specimens obtained during the midluteal phase of tamoxifen cycles to have a maturation delay of 2 or more days in spite of normal levels of progestin and estradiol concentrations.

Using treatment with tamoxifen (10 mg daily for 5 days) in patients with ovulatory menometrorrhagia, El-Sheikha et al.[13] reported that the appearance of the endometrium during the luteal phase of the treated cycle was marked by a pseudodecidual reaction with a disproportionate effect on the stroma, suggestive of an inadequately prepared endometrium by estrogen. Similar results were obtained by Fukushima et al.[9] In a study of the effect of tamoxifen and medroxyprogesterone acetate on human endometrial estrogen and progesterone receptor concentrations, Kokko et al.[14] noted a decreasing trend of both estrogen and progestin cytosol receptor concentrations but little effect on nuclear estrogen and progestin receptors. In the same study the administration of medroxyprogesterone acetate together with tamoxifen significantly increased the concentration of endometrial nuclear estrogen receptor over that of control endometrium taken on day 23 of the cycle. They concluded that tamoxifen may inhibit the estrogen-mediated synthesis of progesterone receptors in the endometrium during the early secretory phase of the menstrual cycle, resulting in delayed endometrial maturation despite normal progesterone and estradiol concentrations. In spite of these findings, Fukushima et al.[9] reported successful pregnancies in six of 17 patients treated with a short-term tamoxifen regimen (10 mg daily for 5 days).

Coutinho[15] in 1982 reported on the use of a synthetic antiestrogen/antiprogesterone compound, gestrinone, for the treatment of endometriosis. The compound, a synthetic trienic 19-steroid has an affinity for progesterone receptors and an antiestrogenic effect in spite of the fact that it does not bind estrogen receptors. It was given in a dose of 5 mg twice weekly to women with endometriosis, and the author noted that all the subjects were symptomless by the end of the third month of treatment. These patients, however, became amenorrheic at the end of the second month of treatment. In the same study five of nine women who had the potential and desire to conceive did so over a period of three to 14 months after the discontinuation of the drug.

Tamoxifen was used for the treatment of two cases of endometrial stromal tumors which were positive for estrogen receptors in the tumor tissue.[16] The authors, however, report a deterioration of the patients' conditions with progression of their tumors.

In our study the administration of tamoxifen (10 mg twice daily) did not seem to alter the secretory patterns of luteinizing hormone and follicle-stimulating hormone; moreover, the concentrations of progesterone at or around day 20 of the treatment cycles indicated ovulation during tamoxifen therapy. These results are in agreement with those of Sherman et al.[5] who studied the effect of long-term administration of tamoxifen to premenopausal women.

Although neither of the patients did conceive, both were relatively symptom free during the treatment period, and laparoscopic evidence indicated a complete regression of their endometriotic lesions after 6 months of treatment with tamoxifen.

The fact that the two patients ovulated and thus could

potentially conceive while receiving treatment raises the problem of teratogenicity in the fetus. A careful search of the literature showed a paucity of reports concerning the teratogenic effects of tamoxifen in humans. In rats, Chamness et al.[17] have shown that tamoxifen administered to newborn female animals caused abnormalities in reproductive development. These authors found that vaginal opening occurred early, cycles were absent, and at 4 months of age all ovaries and uteri were atrophic while oviducts showed severe metaplasia with abscess formation.

Similar observations, also in the rat, were made by Clark et al.[18] who noted hypertrophied and hyperplastic oviducts; ovarian, oviductual, and uterine inflammation accompanied by pyometra; and, in some animals, atrophic uteri and ovaries.

Taguchi and Nishizuka[19] treated neonatal mice with a relatively high dose of tamoxifen and have noted that all treated mice developed reproductive tract anomalies. These were characterized by an abnormal urethral opening into the vaginal lumen and a significant reduction in the size of the common cervical canal. In addition, these mice developed evidence of uterine hypoplasia and absence of corpora lutea.

In a recent communication Diver et al.[20] reported on nonspecific congenital abnormalities in fetuses inadvertently exposed to tamoxifen as well as on healthy babies born to patients receiving tamoxifen. They also report that tamoxifen terminates pregnancies in rats and rabbits; however, in doses that do not do so, no teratogenic effects were found. Deformation or rib cage and altered ossification patterns in the rat were ascribed to uterine pressure effects resulting from inhibition of the estrogenic effect on the pregnant uterus. These multiple deformities were found to disappear after birth.[20]

In our review of the literature we found no reports that tamoxifen is associated with an increase in the incidence of any malignancy in humans. Authors who have used tamoxifen to induce ovulation with a successful pregnancy outcome have not reported on any fetal abnormalities. It must be remembered, however, that these authors used tamoxifen for a short term only, and a number of pregnancies did end in early abortions.[9,21]

It is our conclusion that the use of tamoxifen for the treatment of endometriosis may be useful in a number of situations: (1) Tamoxifen offers symptomatic relief of pain with minimal side effects compared to danazol treatment. (2) It could certainly be used to reduce endometriotic tumors and lesions before definitive surgical treatment. (3) It is relatively inexpensive. (4) Since tamoxifen does not seem to inhibit ovulation, its administration to women suffering from infertility secondary to endometriosis may help in allowing these women to conceive. However, further studies are required to determine its teratogenic effect, if any, on the human fetus before it could be used on a large scale for this purpose.

In view of this lack of knowledge regarding teratogenicity, we have modified our protocol in subsequent trials in women with the potential risk of conceiving while receiving treatment (Behelak and Haber, manuscript in preparation) while simultaneously continuing studies on women not at risk for pregnancy to determine the efficacy of the drug when used intermittently, or with varying doses, to treat lesser grades of endometriotic lesions.

Exaggerated gonadotropin response to luteinizing hormone–releasing hormone in amenorrheic runners

Janet Yahiro, Ph.D., Allan R. Glass, M.D., William B. Fears, M.D., Earl W. Ferguson, M.D., Ph.D., and Robert A. Vigersky, M.D.
Bethesda, Maryland, and Washington, D. C.

Most studies of exercise-induced amenorrhea have compared amenorrheic athletes (usually runners) with sedentary control subjects. Such comparisons will identify hormonal changes that develop as a result of exercise training but cannot determine which of these changes play a role in causing amenorrhea. To obviate this problem, we assessed reproductive hormone status in a group of five amenorrheic runners and compared them to a group of six eumenorrheic runners matched for body fatness, training intensity, and exercise performance. Compared to the eumenorrheic runners, the amenorrheic runners had lower serum estradiol concentrations, similar basal serum luteinizing hormone and follicle-stimulating hormone concentrations, and exaggerated responses of serum gonadotropins after administration of luteinizing hormone–releasing hormone (100 μg intravenous bolus). Serum prolactin levels, both basally and after thyrotropin-releasing hormone administration (500 μg intravenous bolus) or treadmill exercise, was similar in the two groups, as were serum thyroid function tests (including thyrotropin response to thyrotropin-releasing hormone). Changes in serum cortisol levels after short-term treadmill exercise were similar in both groups, and serum testosterone levels increased after exercise only in the eumenorrheic group. In neither group did such exercise change serum luteinizing hormone, follicle-stimulating hormone, or thyrotropin levels. We conclude that exercise-induced amenorrhea is not solely related to the development of increased prolactin output after exercise training. The exaggerated gonadotropin response to luteinizing hormone–releasing hormone seen in amenorrheic runners in comparison with matched eumenorrheic runners is consistent with a hypothalamic etiology for the menstrual dysfunction, analogous to that previously described in "stress-induced" or "psychogenic" amenorrhea. (AM J OBSTET GYNECOL 1987;156:586-91.)

Key words: Exercise, amenorrhea, luteinizing hormone–releasing hormone

Secondary amenorrhea is common in women who exercise intensively, such as long-distance runners and ballet dancers, but the mechanism of exercise-associated menstrual irregularity has not been conclusively established. Etiologic factors that have been suggested as having significance in this disorder include a decrease in body fatness, an "energy drain" caused by increased energy output, augmented prolactin release following exercise, hyperandrogenism, excess psychological stress, and increased central nervous system β-endorphin activity. The differences in conclusions among these studies may reflect in part the differences in subject selection and the lack of an appropriately matched control group. The purpose of the current study was to determine the hormonal abnormalities specifically associated with exercise-induced amenorrhea. To do this we compared amenorrheic runners to a control group of eumenorrheic runners who were matched for age, percent of body fat, training intensity,

Table I. Anthropometric and exercise data on women runners*

	Eumenorrheic	*Amenorrheic*
Age (yr)	28.8 ± 4.6	29.4 ± 6.1
Body fat (%)	15.9 ± 6.6	12.2 ± 5.7
Training intensity (miles/wk)	51.8 ± 18.8	46.3 ± 19.7
Training performance (min/mile)	7.7 ± 0.5	8.7 ± 0.8
Time on treadmill (min)	14.6 ± 2.3	13.2 ± 0.8
Oxygen consumption (ml/kg · min)		
Resting	3.0 ± 0.8	2.1 ± 0.9
Maximal during exercise	52.9 ± 6.0	46.2 ± 4.2

*Mean ± SEM. No statistical difference was observed between the two groups for any parameter.

and level of fitness (maximum oxygen consumption). By contrast, previous studies using sedentary women as controls have not been able to distinguish which of the hormonal changes related to exercise training might be important in leading to amenorrhea.

Methods

Subjects. Six eumenorrheic runners (6 months or more of regular menses) and five amenorrheic runners (6 months or more without menses) were recruited from various running clubs based in Washington, D.C. The groups were matched as closely as possible for age, fatness, and running ability (Table I). Four of five amenorrheic runners were nulliparous as compared to three of six eumenorrheic runners. Although none of the runners was amenorrheic before acquiring an interest in running, two of six eumenorrheic runners had a history of oligomenorrhea in the distant past, compared to four of five amenorrheic runners. One amenorrheic runner reported that menses would resume if she dropped her weekly mileage below 40 miles per week, but she had not done so in over 2 years. None of the subjects had taken oral contraceptives for at least 2 years, and no subject took any medication regularly. All eumenorrheic runners were tested in the early follicular phase of their menstrual cycle (days 2 to 7). All women were instructed to fast for 12 hours and refrain from exercise for 24 hours before testing. Informed consent was obtained before all studies, and this study was approved by our institutional review board.

Exercise study. Each runner exercised on a treadmill using the Bruce protocol to maximum oxygen consumption as determined by a Beckman Metabolic Measurement Cart (Beckman Instrument Inc., 3900 River Road, Schiller Park, IL 60176). Before the exercise period, subjects were allowed to relax in an armchair while control blood samples were obtained at −30 and 0 minutes. Oxygen consumption, carbon dioxide production, and electrocardiographic changes were monitored continuously during exercise, and blood samples were obtained at 0, 15, 30, 45, and 60 minutes after completion of exercise. Basal and maximal oxygen consumption were similar in the amenorrheic and eumenorrheic groups (Table I). Blood was allowed to clot at room temperature, and the serum was frozen at −20° C until analysis. Each sample was analyzed by radioimmunoassay for luteinizing hormone, follicle-stimulating hormone, thyroid-stimulating hormone, prolactin, testosterone, and cortisol. All samples were measured in the same assay run. Intra-assay variation was <10% for all assays. Postexercise hormone values were corrected for changes in plasma volume. Percent of body fat determinations were obtained by use of the skin fold thickness method.

Luteinizing hormone–releasing hormone/thyrotropin-releasing hormone test. On the morning after the exercise study, serum luteinizing hormone, follicle-stimulating hormone, thyroid-stimulating hormone, and prolactin were measured at −30, −15, 0, 15, 30, 45, 60, 90, and 120 minutes after the administration of luteinizing hormone–releasing hormone (100 μg) and thyrotropin-releasing hormone (500 μg) given as a single intravenous bolus. Serum estradiol, serum progesterone, and serum thyroxine levels and T_3 resin uptake were also measured on basal samples.

Data analysis. Basal hormone levels and the responses to exercise, luteinizing hormone–releasing hormone, and thyrotropin-releasing hormone in the study groups were compared by the Wilcoxon rank sum test.

Results

Basal serum luteinizing hormone, follicle-stimulating hormone, testosterone, progesterone, and cortisol concentrations were similar in the amenorrheic and eumenorrheic runners, while serum estradiol level was lower in the amenorrheic group (Table II). The response of serum luteinizing hormone and follicle-stimulating hormone to luteinizing hormone–releasing hormone (100 μg) was assessed by both the peak gonadotropin level attained as well as the area under the curve. The luteinizing hormone area under the curve after luteinizing hormone–releasing hormone was greater in the amenorrheic group (Table II), and although there was more variability in the amenorrheic group (range of responses, 2958 to 10225 mIU ·

Table II. Hormone levels in exercise-induced amenorrhea*

	Eumenorrheic	*Amenorrheic*
Basal levels		
Serum luteinizing hormone (mIU/ml)	12.1 ± 2.2	11.9 ± 3.7

Peak after thyrotropin-releasing hormone	14.2 ± 1.4	22.9 ± 4.0

*Mean ± SEM.

min/ml; range in eumenorrheics 1581 to 3025 mIU · min/ml), all but one of the amenorrheic group had a response greater than the highest value seen in the eumenorrheic group. The luteinizing hormone peak level also appeared greater in the amenorrheic group, but this difference did not attain statistical significance. Similarly, the peak follicle-stimulating hormone level after luteinizing hormone–releasing hormone was greater in the amenorrheic group (Table II), but the follicle-stimulating hormone area under the curve was not statistically different in the two groups.

Basal serum prolactin and the prolactin response to thyrotropin-releasing hormone administration (500 μg) were not different in the amenorrheic and eumenorrheic runners (Table III). Similarly, the exercise-induced rise in serum prolactin was also not different in the two groups (Table III). Thyroid function tests, including the thyroid-stimulating hormone to thyrotropin-releasing hormone, were comparable in the two groups (Table III). Postexercise serum levels of luteinizing hormone, follicle-stimulating hormone, thyroid-stimulating hormone, testosterone, and cortisol were the same in the amenorrheic and eumenorrheic groups (Table IV); cortisol showed a significant rise with exercise in both groups, while serum testosterone was significantly increased over preexercise values only in the eumenorrheic group.

Comment

With the rising interest of American women in exercise programs, the incidence of exercise-related amenorrhea has increased over the past several years. Despite intensive study in recent times, the mechanism of amenorrhea that develops during heavy aerobic exercise remains unestablished. Multiple factors, both hormonal (hyperprolactinemia, androgen excess) and nonhormonal (weight loss, low body fat, energy drain, stress) have been proposed as having an etiologic role in exercise-induced amenorrhea. To establish the role of a hormonal or other abnormality in causing runner's amenorrhea requires a comparison of amenorrheic and nonamenorrheic runners in order to exclude those changes resulting from exercise training which are unrelated to the development of amenorrhea. This type of comparison is also needed to settle a major unanswered question in this area: Does the development of

exercise-induced amenorrhea in some women reflect an abnormal hormonal response to exercise training which is seen only in those amenorrheic women, or does exercise training produce a similar hormonal alteration in all women, with amenorrhea developing only in those with preexisting abnormalities of endocrine function? For example, the suggestion that amenorrheic runners have a higher incidence of menstrual abnormalities before beginning their training supports the concept of a population subset that is peculiarly sensitive and predisposed to exercise-induced amenorrhea. However, the ability of increased exercise training to cause menstrual abnormalities in an otherwise unselected group suggests that prior abnormality of pituitary-ovarian function may not be necessary for development of exercise-induced amenorrhea.[1]

Hyperprolactinemia is a well-recognized cause of amenorrhea. The finding that female runners showed a rise in serum prolactin after acute exercise, but sedentary women did not,[2] raised the possibility that amenorrhea in women runners occurred because they developed the ability to increase serum prolactin after exercise, with menstrual disruption resulting from this intermittent hyperprolactinemia. Such a role for increased prolactin output was supported by the finding that thyrotropin-releasing hormone-induced prolactin release increased as women increased the intensity of exercise.[3] However, comparisons of amenorrheic and eumenorrheic runners showed that the prolactin response to acute exercise was not greater in the amenorrheic group[2, 4] and amenorrheic and eumenorrheic runners did not differ in basal serum prolactin.[2] Likewise, our study showed no difference between amenorrheic and eumenorrheic runners in basal serum prolactin or in the serum prolactin response to acute exercise or to thyrotropin-releasing hormone. Thus, although increased prolactin output may be a consequence of exercise training, the similarity of prolactin response in amenorrheic and eumenorrheic runners suggests that hyperprolactinemia by itself does not cause runner's amenorrhea. We cannot exclude the possibility that the increased prolactin output related to exercise training may induce amenorrhea in a subset of the population with increased sensitivity to prolactin's effects on menstrual function.

Androgen excess is associated with menstrual abnormalities under a variety of circumstances, such as polycystic ovarian disease. Initial findings of elevated basal serum testosterone or exercise-induced increases in serum testosterone in amenorrheic runners raised the possibility that transient or persistent hyperandrogenism might cause the amenorrhea. However, exercise results in hemoconcentration, and in our study there was no change in serum testosterone after exercise in amenorrheic runners after correction for changes in plasma volume, although such an exercise-induced increase was noted in eumenorrheic runners. Others have failed to find exercise-induced increases in serum testosterone in amenorrheic runners,[4] and neither we nor others[4] have found increases in basal serum testosterone concentrations in this group.

Much attention has been focused on gonadotropin levels in women with exercise-induced amenorrhea. In comparison with sedentary women, amenorrheic runners have generally been found to have normal[2, 5, 6] or reduced[4, 7] basal serum gonadotropin levels. Likewise, in two previous studies in which nonamenorrheic runners, studied in the late follicular or late luteal phases, were compared to sedentary controls, reductions were observed in the gonadotropin response to luteinizing hormone–releasing hormone.[5, 8] By contrast, in our study, the only one in which responses in amenorrheic runners were compared to those in eumenorrheic runners matched for fatness and fitness (studied in the early follicular phase), the amenorrheic runners had greater gonadotropin responses to a large bolus dose of luteinizing hormone–releasing hormone than did the eumenorrheic runners. Similarly, gonadotropin responses to lower doses of luteinizing hormone–releasing hormone in severely oligoamenorrheic runners were also greater than in sedentary controls,[6] and an earlier report also described one amenorrheic runner with an exaggerated gonadotropin response to luteinizing hormone–releasing hormone.[7] Such hyperresponses to luteinizing hormone–releasing hormone are unlikely to be due to primary ovarian failure, since basal serum gonadotropins were not elevated and estradiol responses to luteinizing hormone–releasing hormone were reported to be normal.[6] These exaggerated gonadotropin responses to luteinizing hormone–releas-

ing hormone are similar to those reported previously in "hypothalamic,"[9] "psychogenic,"[10] or "stress"[11] amenorrhea, although previous studies have differed on whether amenorrheic runners are subject to an unusual amount of stress. In contrast, the gonadotropin responses to luteinizing hormone–releasing hormone in amenorrhea associated with weight loss, although variable, are often reduced. The finding of hormonal differences between eumenorrheic and amenorrheic runners may suggest that the latter have an idiosyncratic hormonal response to exercise training rather than simply having an underlying hypothalamic-pituitary-ovarian axis which is more vulnerable to perturbation by the exercise-induced hormonal changes occurring in all women.

Pituitary output of gonadotropin depends on the frequency and magnitude of pulsatile luteinizing hormone–releasing hormone output from the hypothalamus as well as the pituitary sensitivity to luteinizing hormone–releasing hormone. The latter, in turn, depends strongly on the level of chronic luteinizing hormone–releasing hormone release (the self-priming effect of luteinizing hormone–releasing hormone) as well as on gonadal steroids, such as estradiol, which can have both positive and negative feedback effects on pituitary gonadotropin output. Several aspects of this scheme have been studied in amenorrheic runners. In particular, recent emphasis has been placed on the findings that amenorrheic runners have reduced frequency of luteinizing hormone–releasing hormone secretion[6] and that acute exercise can reduce the frequency of luteinizing hormone–releasing hormone secretion.[12] However, since eumenorrheic runners also have reduced frequency of pulsatile luteinizing hormone–releasing hormone secretion[13] and some amenorrheic runners have normal rates for pulsatile luteinizing hormone–releasing hormone secretion,[6] it appears that reduced frequency of luteinizing hormone–releasing hormone secretion alone may not be a sufficient explanation for runner's amenorrhea.

Consequently, attention must also be focused on the pituitary sensitivity to luteinizing hormone–releasing hormone and the factors that affect it, particularly the effect of gonadal steroids. Women with secondary amenorrhea have been reported to be hypersensitive to the negative feedback effects of estradiol.[14] Since estrogen can increase the amount of pituitary luteinizing hormone in the "storage" pool,[15] which can be released after large doses of luteinizing hormone–releasing hormone such as that used in the current study, such estrogen hypersensitivity might be expected to produce enhanced gonadotropin responses to luteinizing hormone–releasing hormone, such as we have reported. Moreover, since estrogen also may reduce luteinizing hormone secretion from the acutely releasable pituitary pool,[15] from which might come the luteinizing hormone released from the pituitary by the small endogenous luteinizing hormone–releasing hormone pulses seen in amenorrheic runners, estrogen hypersensitivity might result in reduced gonadotropin output and amenorrhea. Thus it is possible that runner's amenorrhea develops as a result of the combination of reduced luteinizing hormone–releasing hormone secretion and/or increased pituitary sensitivity to estrogens. Alternatively, development of exaggerated gonadotropin responses to luteinizing hormone–releasing hormone may simply be a consequence of deficient luteinizing hormone–releasing hormone output per se. For example, when pulsatile luteinizing hormone–releasing hormone support is withdrawn from patients with hypogonadotropic hypogonadism, subsequent gonadotropin responses to bolus luteinizing hormone–releasing hormone can be supranormal.[16] Our data provide no specific information to confirm or refute these theories, which must remain speculative in the absence of confirmatory data. However, our study does define specific abnormalities in amenorrheic runners, confirming the probable hypothalamic-pituitary origin of exercise-induced amenorrhea and suggesting that it may be different from that seen with weight loss.

We would like to thank Mrs. Estelle C. Coleman for expert editorial assistance.

The effect of low-dose oral contraceptives on cardiorespiratory function, coagulation, and lipids in exercising young women: A preliminary report

Morris Notelovitz, M.D., Ph.D., Chris Zauner, Ph.D., Lynda McKenzie, R.N., M.Ed., Yvonne Suggs, R.N., Carol Fields, M.P.E., and Craig Kitchens, M.D.
Gainesville and Miami, Florida

A study was undertaken to determine whether low-dose oral contraceptive usage would negate the beneficial effect of exercise on cardiorespiratory fitness, lipid and lipoprotein levels, and coagulation. Twelve exercising women were randomly allocated to groups of either oral contraceptive users or non–oral contraceptive users. When compared with results in the control group, maximal oxygen uptake ($ml/kg^{1} \cdot min^{1}$) decreased significantly in the oral contraceptive users during the 6-month period of observation. This was associated with an 8% decrease in both the oxygen uptake (2.34 to 2.17 L/min) and the oxygen pulse (12.1 ± 3.2 to 11.2 ± 2.2 ml/beat). The serum cholesterol, triglycerides, high-density lipoprotein/cholesterol, and high-density lipoprotein subfractions 2_a and 2_b levels were not altered. A significant increase in plasminogen activity was found in the oral contraceptive users: values increased from a coherent time average of 3.8 ± 0.5 U/ml at baseline to 5.7 ± 0.7 U/ml at 6 months; values returned to baseline levels 1 month after stopping the oral contraceptives (coherent time average of 3.9 ± 0.6 U/ml; $p < 0.0001$). No other significant changes were noted in the coagulation and anticoagulation factors studied. Low-dose oral contraceptive usage is associated with a decrease in functional aerobic capacity, but it does not impinge on the hemostatic mechanism or lipid-lipoprotein metabolism. (Am J Obstet Gynecol 1987;156:591-8.)

Key words: Oral contraceptives, coagulation, fibrinolysis, lipids, lipoproteins, exercise, cardiorespiratory function

Exercise is said to be "cardioprotective." Although this effect may not translate into longevity for all who exercise, there is compelling evidence that the exercise level is indeed inversely related to cardiovascular and respiratory morbidity and mortality.[1] Premenopausal women appear to have a relative immunity to cardiovascular disease. The use of oral contraceptives, by their potential adverse effect on the lipid and lipoprotein profile and on the coagulation system, could reduce this physiologic advantage and negate positive changes induced by exercise. Since much of the earlier information in the literature is based on "high-dose" oral contraceptive usage in nonexercising populations, a

Table I. Characteristics of patients studied

Oral contraceptive use	*Age (yr)*	*Height (cm)*	*Weight (kg)*	
			Baseline	*Conclusion*
Nonusers (group 1)	24.3 ± 3.0	165.2 ± 7.1	57.3 ± 8.0	57.5 ± 8.2
Users (group 2)	24.5 ± 3.2	166.7 ± 3.0	57.5 ± 6.5	59.3 ± 6.3

study was initiated to evaluate the effect of low-dose oral contraception on cardiorespiratory function, lipids and lipoprotein metabolism, and coagulation in exercising young women.

Material and methods

Subjects were recruited from students attending the University of Florida who met the following criteria: they were required to be between 20 to 30 years of age and not currently using oral contraceptives. Their exercise program involved training at least three times per week; runners needed to cover at least 15 miles a week and swimmers 6500 yards a week.

Twelve young women who met the above criteria participated in and completed the study. They had all been in training for more than 1 year. Subjects were randomly assigned into a birth control (n = 6) or a diaphragm/intrauterine device group (n = 6). The oral contraceptive used (Ovcon 35, Mead Johnson, Evansville, Indiana) contained 35 μg of ethinyl estradiol and 0.4 mg of norethindrone. Diaphragm and/or intrauterine devices were fitted for women randomized into the control group. The nonusers of steroid contraceptives (group 1) were closely matched with oral contraceptive users (group 2) (Table I). They were all in good health without evidence of heart or lung disease and without contraindications for oral contraceptive use.

The cardiorespiratory fitness tests were performed at The Center for Physical and Motor Fitness, University of Florida, and the metabolic studies at The Center for Climacteric Studies, Inc., Gainesville. After signing informed consent, each subject had a detailed physical and gynecologic examination. Blood pressure was measured in the sitting position after a 10-minute rest period. The systolic pressure was recorded with the appearance of the first sound, and the diastolic blood pressure with the disappearance of the second sound (phase V Korotkoff). The graded exercise test took place between 6 and 8 AM after a 12-hour complete fast and at least 8 hours of sleep the previous night. The treadmill protocol of Balke et al.,[2] modified for women, was used. The treadmill speed was a constant 3.0 mph and the work task began at a 0% treadmill grade. Elevations in the grade were made at the end of each minute of walking. The first increase was 2%, with subsequent elevations of 1%. After 5 minutes of walking, the subject was performing at 3.0 mph at 5% treadmill grade. This work task was submaximal for all subjects. During the submaximal period, they were evaluated for expired volume in 1 minute, frequency of breathing, tidal volume, oxygen uptake, heart rate, oxygen pulse, and ventilatory equivalent. An automated system (Metabolic Measurements Cart, Beckman Instruments, Schiller Park, Illinois), which performs infrared analysis and polarographic measurement of carbon dioxide and oxygen, respectively, was used to assess all parameters, except for heart rate, which was monitored by palpation.

After measures at submaximal exercise, each subject was brought to maximal physical effort by continuation of the modified protocol of Balke et al.[2] until complete fatigue was proclaimed. The oxygen uptake was measured at this point (maximal oxygen uptake). Two submaximal and two maximal tests were performed on separate days. The assessment reflective of the highest oxygen uptake measure provided the data for analysis. Test days were separated by no fewer than 3 days and no more than 7 days. Each subject was tested before receiving contraception (baseline), and at the conclusion of their respective "treatment."

Blood samples were obtained at the start of the study, at 3 and 6 months of oral contraceptive usage and after oral contraceptives had been suspended for 1 month—the 7-month interval. The sampling was performed at The Center for Climacteric Studies, Inc., between 8 and 9 AM after an overnight fast of 12 hours. The blood for the coagulation profile was collected in tubes containing 3.8% sodium citrate and centrifuged immediately at 4500 rpm for 5 to 10 minutes. Serum was separated and kept frozen at −70° C until analysis. All samples were drawn in the second half of the menstrual cycle.

Tests representative of both coagulation and anticoagulation were performed. The prothrombin time, activated partial thromboplastin time, and the thrombin time were measured by the fibrometer method. Clottable fibrinogen was estimated by the Clauss method.[3] Fibrinogen antigen, plasminogen antigen, α_1-antitrypsin antigen, α_2-macroglobulin antigen, and antithrombin III antigen were determined by radial immunodiffusion with use of plates purchased from Calbiochem-Behring, La Jolla, California (m-Partigen). Plasminogen activity, antithrombin III activity, and α_2-antiplasmin activity were determined by fluorome-

tric assays (Protopath, American Dade, Miami, Florida). The variation for Protopath for antithrombin III is 7% and for plasminogen, 5%. All tests were performed by a technician who did not know the identify of the group assignments.

Aliquots of the blood samples were also taken for analysis of serum cholesterol, triglyceride, total high-density lipoprotein, high-density lipoprotein/cholesterol, and high-density lipoprotein subfractions 2_a and 2_b. Serum was obtained by centrifugation for the lipid studies, and the sample divided into two portions. One portion was stored at −60° C until analysis for total cholesterol, high-density lipoprotein/cholesterol, and total triglycerides. The density of the other portion was adjusted to 1.21 gm/cc, with use of sodium bromide. One hundred fifty microliters of the adjusted solution was placed in a Beckman Airfuge centrifuge tube and spun at top speed for 5 hours. After centrifugation 6 μl was removed from the top of the tube and placed directly on a 4% to 30% gradient polyacrylamide gel (Pharmacia Fine Chemical Co., Piscataway, New Jersey). Electrophoresis was carried out for 18 hours at 125 V constant voltage. After electrophoresis the gels were removed from the cassettes and stained for 20 minutes with a solution of 1% amido black in 25% isopropanol, and 10% acetic acid. After electrophoretic destaining the gels were sliced vertically and scanned at 620 nm with use of a Beckman gel scanning attachment coupled to a Model 25 UV-VIS spectrophotometer. Concentrations of high-density lipoprotein subfractions 2_a and 2_b were determined from the recorded scans with use of a Zeiss MOP3 digital pad coupled to a microcomputer. The area under each region of the scan was taken to be equivalent to the protein concentration present. Standard curves were prepared with use of known amounts of separate purified high-density lipoprotein subclasses. Accuracy of determination of separate subclasses was such that <10% variation existed between duplicate samples.

Total serum cholesterol and high-density lipoprotein/cholesterol were determined with use of the cholesterol-oxidase method (Fisher Scientific Products). Non–high-density lipoproteins were precipitated with use of phosphotungstic acid and magnesium. After centrifugation the cholesterol content of the clear supernatant produced was assumed to represent high-density lipoprotein/cholesterol. Total serum triglyceride concentrations were determined with use of a nicotinamide-adenine dinucleotide–linked enzymatic assay (American Monitor Corporation). All methods were standardized with use of the standard solutions supplied by the manufacturers of test kits.

A final physical examination was performed 1 month after completion of their treatment schedule.

Statistical analysis. The data were analyzed with use of repeated measures analysis of variance to test for overall differences between the observation times (baseline, 1, 6, and 7 months) for each parameter measured. If a significant time effect was noted, Tukey's Studentized range test, also known as the HSD (honestly significant difference) test, was used. If the HSD test failed to show any significant differences despite a time effect, Duncan's multiple range test was used to find which time points were significantly different.[4, 5]

Results

The maximal oxygen uptake is the amount of oxygen taken up by the entire body during maximal physical effort. It reflects the status of the entire oxygen delivery system—heart, lungs, blood vessels, blood pool, and the ability of skeletal and myocardial muscle to extract oxygen from the blood. The maximal oxygen uptake in the oral contraceptive users decreased from 41.2 ± 11.8 $ml/kg^2 \cdot min^1$ to 38.4 $ml/kg^1 \cdot min^1$ (a difference of 7%). The maximal oxygen uptake of the group 1 subjects increased their values from 42.6 ± 2.8 to 45.9 ± 5.8 $ml/kg^1 \cdot min^1$ for the baseline and concluding assessments, respectively ($p < 0.03$). The submax-

imal oxygen uptake was constant at both test intervals in both groups, as were most of the other cardiorespiratory parameters measured. The only other changes of significance were the oxygen pulse values, that is, the volume of oxygen consumed per heart beat. The non–oral contraceptive users increased their values by 9% (12.3 ± 2.3 to 13.4 ± 2.2 ml/beat), while the treated group's values decreased from 12.1 ± 3.2 to 11.2 ± 2.2 ml/beat—a difference of 8% ($p < 0.02$) (Table II). The systolic and diastolic blood pressures were unaltered in both groups throughout the 7-month study period (Table III).

Two changes among the oral contraceptive users were noted among the dynamic tests of coagulation. The prothrombin time decreased during treatment and returned to baseline values 1 month after cessation of oral contraceptive usage ($p < 0.07$) (Table IV); the thrombin time increased significantly ($p < 0.007$) from a baseline value of 14.5 ± 2.0 S to 16.6 ± 2.0 and 16.5 ± 2.9 S at 3 and 6 months, respectively. The values returned to basal levels at 7 months (13.8 ± 1.7 S). All of these changes were within the range of normal for our laboratory.

The results of the inhibitory component of the anticoagulation system (Table V) were considered separately from those involved with fibrinolysis (Table VI). The most significant finding was that there were no changes in either the antithrombin III antigen or antithrombin III activity. A statistically significant ($p < 0.0001$), treatment-related (group 2) increase in one of the minor anticoagulant enzymes, α_1-antitrypsin antigen, was recorded, but the values remained within physiologic levels.

The values for plasminogen activity and antigen were unaltered in the non–oral contraceptive users (group 1) but were significantly increased in the oral contraceptive group. The baseline plasminogen activity values in group 2 subjects (coherent time average of 3.8 ± 0.5 U/ml) increased to 5.2 ± 0.9 U/ml at 3 months and to 5.7 ± 0.7 U/ml at 6 months. After 1 month without therapy the values had decreased to the baseline levels again ($p < 0.0001$). The 3- and 6-month values exceeded the range of normal for our laboratory. The plasminogen antigen results were similarly increased ($p < 0.0001$), but the actual values were within the laboratory's normal range (Table VI). Antiplasmin activity in the oral contraceptive users decreased while receiving treatment: baseline mean values of 82.0% ± 22.0% fell to 64.3% ± 17.0% and 71.9% ± 13.0% at 3 and 6 months of treatment, with a return to normal at 86.5% ± 6.8% after withdrawal from treatment for 1 month. This change was not, however, statistically significant ($p < 0.06$). There was no change in α_2-antiplasmin values of the nonusers of oral contraceptives.

As reflected in Table VII, none of the lipid (cholesterol and triglyceride) and lipoprotein (total high-density lipoprotein; high-density lipoprotein/cholesterol; high-density lipoprotein subfraction 2_a and 2_b) parameters analyzed were altered during the course of the study. This was true for both the oral contraceptive users (group 2) and the nonusers of oral contraceptives (group 1).

Comment

There is a remarkable interest among women to participate in various types of exercise conditioning programs in order to enhance their physical fitness and to maintain their health. Earlier studies have shown that consistent and meaningful exercise is associated with a lower incidence of cardiovascular-related disease[1] and that this can be measured objectively by various parameters, for example, a lowering of and a maintenance of blood pressure in regularly exercising men and women[6]; an improvement in fibrinolytic activity[7]; the well-documented enhancement of the cardioprotective lipoprotein high-density lipoprotein/cholesterol[8] and increases in functional aerobic capacity determined by graded exercise testing.[9]

Another significant health care change for women in recent times has been the use of oral contraceptives. Apart from the efficacy of oral contraceptives in family planning, their long-term use has resulted in many noncontraceptive advantages: a decrease in benign breast disease, ovarian tumors, anemia, and pelvic inflammatory disease, to name a few.[10] However, earlier studies showed that oral contraceptives may have an adverse effect on the cardiovascular system as evidenced by an increased incidence of thrombogenic cardiovascular events, changes in the coagulation/anticoagulation system,[11] a lowering of high-density lipoprotein/lipoproteins,[12] and the development of hypertension.[13] Much of the data regarding these side effects were from studies in women on relatively high-dose estrogen/progestogen preparations, but their physical activity level was rarely commented on. It can be safely assumed that the majority were not involved in formal exercise programs.

The present study has illustrated that the potential benefits of exercise are affected by low-dose steroid contraceptives. Our subjects (according to accepted normative data) were physically fit, since their mean maximal oxygen uptake values, 42.6 ± 2.8 (group 1) and 41.2 ± 11.8 (group 2) $ml/kg^{-1} \cdot min$, were within the range of normal for women of their age: 38 to 48 $ml/kg^{-1} \cdot min^{-1}$. All of the subjects maintained that they continued with their regular exercise program, yet the women receiving oral contraceptives as a group had a significant decrease in maximal oxygen uptake after 6 months of oral contraceptive use—from 41.2 ± 11.8 to 38.4 ± 9.8 $ml/kg^{-1} \cdot min^{-1}$ ($p < 0.03$). Despite an increase in the subjects' weight, which could have accounted in part for this result (from a baseline value of 57.5 ± 6.5 kg to 59.3 ± 6.3 kg), the oxygen uptake at the respective intervals decreased from 2.4 ± 0.67 L/min and 2.2 ± 0.5 L/min (8%), while the oxygen pulse showed a similar decrease (8%) from 12.1 ± 3.2 to 11.2 ± 2.2 ml/beat. The reduction in maximal oxygen uptake did not affect the subjects' regular exercise routines, and the submaximal oxygen uptake, which is

reflective of the energy demands of everyday activity, was unaffected.

Montes et al.[14] also found (as we did) that low-dose oral contraceptives did not have an adverse effect on the ventilatory response to treadmill exercise; in fact, they reported that the oral contraceptive had a moderate ventilatory stimulating effect (not found in this study) and attributed this to the progestin component. Their subjects were all untrained but were also studied for 6 months.

Systolic and diastolic blood pressures remained at normal levels throughout the study. Although the progestogen component of oral contraceptives has been related to elevations in blood pressure, this phenomenon is much less frequent in the lower-dose oral contraceptives.[13] Exercise also has a stabilizing effect on blood pressure,[6] and it has been shown that men and women who are highly fit are less likely to develop hypertension later in life. Although the duration of observation was short and the number of subjects studied was small, low-dose oral contraceptive use did not have a negative impact on the blood pressure of these physically fit young women.

Exercise has an anticoagulant effect and has even been shown to act synergistically with some oral contraceptives to increase fibrinolytic activity, as measured by plasminogen activator, over and above that induced by the oral contraceptive itself.[15, 16] Hedlin et al.[15, 16] in a cross-sectional study that compared 12 women on a medium-dose oral contraceptive (0.05 mg of ethinyl estradiol; 1 mg of ethynodiol diacetate) with 13 matched controls showed that exercise significantly increases both antithrombin III activity and plasminogen activator levels. Their study was based on the influence of acute exercise. In our study involving physically fit women at rest, an increase in plasminogen activity was noted after 3 and 6 months of treatment with the low-dose oral contraceptives. The levels reached, a coherent time average of 5.2 ± 0.9 and 5.7 ± 0.7 U/ml, were well in excess of the reference range for our laboratory (2.4 to 3.8 U/ml) (Table III). The values returned to basal levels 1 month after cessation of oral contraceptive use (3.9 ± 0.6 U/ml). Plasminogen activity levels were unaffected throughout the study in group 1 subjects.

Antiplasmin (α-antiplasmin inhibitor) is a protease that inhibits 35% of the plasmin generated from plasminogen and thus has a most important biologic role in homeostasis. A decrease in this fraction liberates plasmin activity and has been known to cause a dangerous bleeding diathesis. Although the decreased levels noted in the present study were not statistically significant ($p < 0.06$), the values at 3 and 6 months of treatment (64.3% ± 17.0% and 71.9% ± 13.0%) were beyond our laboratory's normal range, reflecting a potential for a true biologic effect. Huisveld et al.[17] recorded a significant decrease in α_2-plasmin inhibitor activity in female cyclists using oral contraceptives. Their subjects, however, were studied within 1 minute of a bicycle ergometer test; acute exercise is known to stimulate fibrinolytic activity. Given the stable α_2-antiplasmin levels in group 1, the decreased α_2-antiplasmin levels during oral contraceptive use (group 2) and the return to basal levels at the 7-month test interval appears to be a treatment effect. The mechanism is not known, but a similar event in a slightly older population of sedentary women has been observed previously and has been attributed to the progestin in the oral contraceptive.[18]

Antithrombin III accounts for at least 50% of the anticoagulant activity of blood. As summarized elsewhere,[19] a number of studies have shown a statistically significant decrease in antithrombin III antigen and activity in women receiving combination oral contraceptives. There are a number of reasons for this, one of which is dose-related; the lower-dose oral contra-

ceptives (those containing 30 to 35 μg of ethinyl estradiol) are associated with either no significant change, or a much reduced effect when compared with higher-dose preparations (≥50 μg of ethinyl estradiol). The level at which antithrombin III would allow thrombus formation is thought to be at 50% of its normal activity. The antithrombin III activity levels in both the treated and control groups remained in excess of 100% throughout the duration of the study (Table V). Exercise-induced increases in this parameter were not observed.[16, 17] The less potent thrombin inhibitors, α_1-antitrypsin and α_2-macroglobulin, may also be regarded as "clot preventors," and they too were either unaffected or increased: α_1-antitrypsin antigen increased significantly ($p < 0.0001$) in group 2 women at 3 and 6 months of treatment (Table V).

Prothrombin times and activated partial thromboplastin times represent activity of the extrinsic and the intrinsic pathways of the coagulation cascade, respectively. Oral contraceptive usage resulted in a decrease in prothrombin time ($p = 0.07$) and a significant decrease in thrombin time ($p < 0.007$). This parameter reflects the conversion of fibrinogen to fibrin and was associated with an observed (but nonsignificant) increase in fibrinogen antigen which persisted for a month after treatment had been stopped. These changes are well within the reference range for our laboratory, and it is unlikely that they represent a change that would result in a biologic effect.

Despite the difficulty of interpreting the clinical effect of the hematologic changes induced by oral contraceptives and the fact that there are no tests that can actually predict clot formation,[20] it is still reasonable to conclude that an increase in overall fibrinolytic activity should counteract thrombus formation.[19] Our study did not set out to determine the effect of exercise per se on the hemostatic mechanism. The results show that the use of oral contraceptives had no adverse effect on the dynamic tests of coagulation and actually enhanced certain factors that may have a proanticoagulant effect.

It is well established that the risk of developing coronary heart disease is inversely related to the level of high-density lipoprotein/cholesterol.[21] This fraction is lowered by oral contraceptives in direct proportion to the potency (or dose) of the progestogen[12] but is increased by exercise.[8] Williams et al.[8] have shown that elevated plasma concentrations of high-density lipoprotein/cholesterol occur only when a threshold exercise level of 10 miles per week is run and is maintained for at least 9 months. It is also important to ensure that study participants are actively training when tested, since a 3-day test can reverse exercise-induced elevations of high-density lipoprotein/cholesterol and lowered serum cholesterol values.[22] All of our study subjects met these requirements. By lowering the progestogen component or the ratio of the progestogen to estrogen, one can anticipate a lesser effect on the high-density lipoprotein/cholesterol moiety.[23] When this regimen is combined with a regular exercise program, no change should therefore occur. This was in fact reflected in the results of the present study. Serum cholesterol and triglycerides, total high-density lipoprotein, high-density lipoprotein/cholesterol and high-density lipoprotein subfraction 2_a levels were unaffected for the entire 7-month duration of the study. The high-density lipoprotein subfraction 2_b level in the oral contraceptive users did show a progressive fall, but the change was not statistically significant. The lipid and lipoprotein levels were compatible with those found in athletes and are in agreement with the study of Gray et al.[24] They studied the effect of oral contraceptives on the lipid profile (serum cholesterol, triglyceride, high-density lipoprotein/cholesterol and low-density lipoprotein/cholesterol) of five women runners and compared these results with six runners who were not receiving oral contraceptives. No significant differences in the lipid profile of the two groups were found in this cross-sectional study.

Given the small sample size and a relatively short duration of observation, it would be unwise to project the conclusion of this study to the general population. Nevertheless, we have shown that low-dose oral contraceptives given to physically fit young women did decrease their functional aerobic capacity and could result in a decrease in the maximal performance ability of athletes. There was no adverse effect on the hemostatic mechanism or the lipid-lipoprotein profile.

The statistical analysis was performed by Jane Pendergast, Ph.D., Department of Biostatistics, University of Florida College of Medicine, and the lipid and lipoprotein analysis by Tom Grow, Ph.D., Department of Basic Dental Science, College of Dentistry, University of Florida.

Reassessment of White's classification and Pedersen's prognostically bad signs of diabetic pregnancies in insulin-dependent diabetic pregnancies

Michael P. Diamond, M.D., Sheron L. Salyer, R.N.C., William K. Vaughn, Ph.D., Robert Cotton, M.D., and Frank H. Boehm, M.D.

Nashville, Tennessee

The classification systems developed over 20 years ago by White and Pedersen identified diabetic pregnancies at increased risk for perinatal mortality. To assess whether these same criteria would currently be valid, 199 diabetic pregnancies with deliveries from 1977 to 1983 were reviewed. Perinatal mortality rates for White's Classes B gestational (n = 72), B (n = 27), C (n = 67), and D + F + R (n = 33) were 2.9%, 11.1%, 14.9%, and 21.1%, respectively ($p < 0.05$). White's classes were also predictive of pulmonary morbidity (12.5%, 18.5%, 22.4%, and 42.4%, respectively). The presence of one or more of the prognostically bad signs of pregnancy (n = 76) increased the perinatal mortality rate to 17.1% versus 7.3% among insulin-dependent diabetic pregnancies without prognostically bad signs ($p < 0.05$). The presence of any prognostically bad signs of pregnancy was also predictive of pulmonary morbidity in general (31.6% versus 16.3%, respectively) and hyaline membrane disease in particular (13.2% versus 4.1%, respectively). Thus with use of modern obstetric management and medical care of the pregnant diabetic patient, both White's classification and Pedersen's prognostically bad signs of pregnancy continue to be predictive of perinatal mortality. (Am J Obstet Gynecol 1987;156:599-604.)

Key words: Diabetes, pregnancy, White's classification, reassessment, Pedersen's prognostically bad signs

In the late 1940s White devised a classification of diabetic pregnancies which established more precise predictions of the perinatal mortality rate.[1] This system was based on prepregnancy characteristics of the mother, namely, the duration of diabetes, the age of onset, and the presence or absence of diabetic vascular complications. Subsequently, in the 1960s Pedersen and associates described another system for predicting perinatal mortality in diabetic pregnancies, which complemented White's classification. This second system identified a poorer outcome in those pregnancies in which one of the following four prognostically bad signs of pregnancy developed during pregnancy: diabetic ketocidosis, pregnancy-induced hypertension, pyelonephritis, or maternal neglect.[2, 3]

However, since the introduction of these predictive classification systems, the medical care, obstetric management, and neonatal treatment of the pregnant diabetic patient and her infant changed dramatically.[4-9] Modern advances include the use and application of ultrasound, assessment of fetal well-being by nonstress tests, oxytocin challenge tests, and biophysical profiles, the prediction of fetal lung maturity, and advances in treatment of prematurity and neonatal respiratory distress.[4] Consequently, questions have arisen as to whether the current application of White's classification and Pedersen's prognostically bad signs continues to possess predictive value in the identification of pregnancies at increased risk for perinatal mortality.

This report examines the value of these classification systems in the prediction of perinatal mortality in insulin-dependent diabetic pregnancies. Furthermore, it evaluates whether White's classification or Pedersen's prognostically bad signs are of predictive value in identifying infants with an increased risk of developing the various types of neonatal morbidity to which infants of diabetic pregnancies are predisposed.

Material and methods

The patient population for this report consisted of all insulin-dependent diabetic women who delivered during a 7-year period from January 1, 1977, to December 31, 1983, at Vanderbilt University Medical Center, a tertiary referral hospital. Data collection was accomplished by a review of the medical records of these women and their infants.

From the Division of Biostatistics and the Departments of Obstetrics and Gynecology and Pediatrics, Vanderbilt University Medical Center.

Presented in part at the Twelfth Annual Congress of the International Diabetes Federation, Madrid, Spain, September 23-28, 1985.

Received for publication February 21, 1986; revised July 17, 1986; accepted October 17, 1986.

*Numbers in parentheses indicate deaths associated with congenital malformations.

Management of these insulin-dependent diabetic pregnancies has been previously described.[9] Briefly stated, the principle of obstetric care of these women has been an increasing reliance on outpatient management while awaiting development of fetal pulmonary maturity, at which time delivery was initiated. Hospital admissions are now limited to those for obstetric indications or delivery.

The current management plan includes evaluation of glucose homeostasis at the initial presentation for insulin-dependent diabetes or as soon as the need for insulin management of gestational diabetes was determined.[5] This evaluation was performed at home and was composed of 3 days of measuring glucose "day curves." Day curves consisted of blood glucose levels measured in the fasting state and postprandial levels measured 2 hours after breakfast, lunch, and dinner. Target glucose values were <100 mg/dl during fasting and <150 mg/dl after meals. During this introduction period the patients were instructed in the home measurement of day curves by means of Chemstrips (Bio-Dynamics, Indianapolis, Indiana), the composition of an American Diabetes Association diabetic diet of approximately 35 calories per kilogram of ideal body weight, the measurement of urine ketones, the administration of insulin, and the principles of diabetic care. These women subsequently performed a day curve measurement once a week and phoned these results to the nurse clinician who would consult with a physician regarding possible alterations in insulin doses. Insulin administration usually consisted of twice daily injections of a mixture of neutral protamine Hagedorn and regular insulin.

The mainstay of our antepartum fetal monitoring system has been the nonstress test, which is currently performed twice weekly beginning at 32 weeks' gestation and continuing until delivery. (During the first 3 years of the study, nonstress tests were performed weekly.) If fetal well-being could not be established by the nonstress test, evaluation was continued with use of contraction stress tests and biophysical profiles as described previously.[5] Pregnancy was continued until the development of spontaneous term labor or until fetal lung maturity could be established by amniocentesis. After demonstration of pulmonary maturity, delivery was initiated by Pitocin induction or cesarean section depending on the cervical status.

Listing of congenital anomalies and birth injuries was

limited to those identified in the nursery. Diagnosis of neonatal pulmonary morbidity in general and hyaline membrane disease in particular was obtained from the neonatal intensive care unit and based on published criteria.[10] Pulmonary morbidity refers to the occurrence of all types of neonatal pulmonary difficulties including hyaline membrane disease, type II respiratory distress syndrome, pulmonary edema, meconium pneumonitis, and pneumonia. Neonatal morbidity was defined for the purpose of this report as previously described:[9] neonatal hypoglycemia as a glucose level of <40 mg/dl in infants weighing ≥2000 gm and a level of <30 mg/dl in infants weighing <2000 gm; hypocalcemia as a calcium level of <7 mg/dl; hyperbilirubinemia as a bilirubin of ≥12 mg/dl;; polycythemia as a hematocrit of ≥70%; macrosomia as a birth weight greater than the ninetieth percentile at each gestational age.

For the purpose of analysis, White's Class B was subdivided into those women who were not receiving insulin before pregnancy (gestational diabetic patients, Bg) and those receiving insulin before pregnancy (B). During the period of the study an attempt was routinely made to manage cases of gestational diabetes by dietary manipulation alone. Those started on insulin were unable to be managed successfully by diet alone or had markedly elevated fasting blood sugar (usually >120 mg/dl). Classes D, F, and R were grouped together to facilitate statistical analysis. As such, this group represents patients with long-standing diabetes and/or diabetic complications. Statistical analysis was performed by the χ^2 test, Fisher's exact test, and the unpaired t test. All data are expressed as mean ± SEM. Statistical significance was defined as $p < 0.05$.

Results

During the 7 years of this evaluation, 199 women with insulin-dependent diabetes mellitus delivered at Vanderbilt University Medical Center. Grouped by White's classification 99 were Class B, of which 72 were gestational (Bg), and 27 were insulin dependent before pregnancy (B). Sixty-seven were Class C, 20 were Class D, six were Class F, and nine were Class R. Maternal age at the time of delivery decreased in association with advancing White's classification (Table I). In a comparison of the estimated gestational age at the time of delivery among the four groups, the only significant difference was between the Bg and D + F + R groups (37.3 ± 0.3 vs. 35.3 ± 0.7 weeks, respectively; $p < 0.05$). Based on White's classification, there was no

difference in the rate of previous stillbirths or the length of maternal hospitalization during the prenatal and postpartum periods (Table I).

With regard to neonatal morbidity, there was an increased likelihood of admission to the neonatal intensive care unit with advancing White's classification ($p < 0.03$). The length of infant hospitalization was highest in group D + F + R, followed by group C, and finally by both groups Bg and B. There was no difference in Apgar scores at 1 minute, while at 5 minutes the only significant difference was between groups Bg and B. Compared to the D + F + R group, the mean weights of infants in all of the other groups was higher, although this difference was only significant for groups Bg and C. Macrosomia was significantly less common in group D + F + R than in any of the other groups.

There was a significant increase in the rates of neonatal pulmonary morbidity in association with advancing White's classification ($p = 0.0123$). While a similar trend was seen for the occurrence of hyaline membrane disease, it did not reach statistical significance. The rates of hypoglycemia, hypocalcemia, hyperbilirubinemia, and polycythermia were not different between the groups. The rate of congenital anomalies was lowest in the gestational diabetic patients, but there was no statistical significance. The perinatal death rate increased in association with advancing disease according to White's classification. This increase represented increases in both the rate of intrauterine fetal deaths and nursery deaths, although the trend in neither of those groups individually reached statistical significance. (Of the 22 intrauterine and nursery deaths, 13 were due to congenital anomalies incompatible with life.)

Pedersen's prognostically bad signs were identified in 76 pregnancies. The most frequent was pregnancy-induced hypertension, which was identified in 41. Diabetic ketoacidosis occurred in 21 pregnancies; of these infants, seven died intrauterine and one in the nursery. Mothers were characterized as neglectors in 14 pregnancies. Pyelonephritis only occurred during six pregnancies; however, one fetal death was observed in that group.

Table II examines outcome of insulin-dependent diabetic pregnancies grouped by the presence or absence of one or more prognostically bad signs of pregnancy. Mothers with prognostically bad signs were significantly

younger ($p < 0.0005$) and had a greater length of hospitalization ($p < 0.0005$); however, there was no difference in the rate of previous stillbirths or the gestational age at delivery. With regard to neonatal outcome, infants born to pregnancies with a prognostically bad sign were significantly more likely to be admitted to the neonatal intensive care unit ($p = 0.025$), although their total length of hospitalization was not significantly increased. There was no difference in Apgar scores between the two groups, and there was no difference in the birth weights or birth injuries. Polycythemia occurred in 10 infants, all of whom were in the group without prognostically bad signs. There was no difference in the rates of hypoglycemia, hypocalcemia, hyperbilirubinemia, macrosomia, or congenital anomalies. However, pulmonary morbidity in general was significantly increased in the group with prognostically bad signs ($p = 0.0014$), as was the occurrence of hyaline membrane disease in particular ($p = 0.0182$). Finally, the perinatal death rate was significantly higher in the group with prognostically bad signs ($p = 0.0324$). This represented an increased rate of intrauterine fetal death in that group ($p = 0.0029$), which was primarily composed of intrauterine fetal death in women with diabetic ketoacidosis or in neglectors.

Comment

Recognition of the increased risks to which infants of diabetic mothers are predisposed has been described since before the turn of the century.[11] White's classification and Pedersen's prognostically bad signs each characterized diabetic pregnancies, identifying those infants at risk for perinatal mortality.

In her review of 78 fetal deaths in 439 diabetic pregnancies (18%), White[1] concluded that the worst maternal prognostic factor was the degree of vascular disease. Other factors identified included the age of onset of diabetes and its duration. Regarding stillbirths in the diabetic population, White observed that 68% occurred after 35 weeks' gestation, while congenital anomalies were responsible for 15% of the neonatal deaths.

In their report describing 304 diabetic pregnancies Pedersen and Pederson[2] identified a perinatal mortality rate of 18%. Among pregnancies in which a prognostically bad sign was present, the perinatal mortality rate was 32%, as compared to only 8% in pregnancies without prognostically bad signs. Examining the factors that constitute prognostically bad signs individually, the following perinatal mortality rates were identified: pyelorephritis, 41%; diabetic ketoacidosis, 37%; severe toxemia, 38%; less severe toxemia, 24%; neglectors, 38%. White's classification was also found to be predictive of the perinatal mortality rate in their patient population.

The potential quality of diabetic pregnancies can be markedly improved. In a group of patients maintained during pregnancy under meticulous metabolic control, the complications to which infants of diabetics mothers were predisposed were totally eliminated.[12] Other recent reports have also described substantial reductions in the complications of diabetic pregnancies compared to those early reports, with one exception, the continued occurrence of an increased rate of congenital anomalies. The failure to reduce the rate of anomalies is believed to be due to the failure to establish good metabolic control during the period of embryogenesis,[13] since this often occurs before women realize they are pregnant. Further support for this hypothesis was a report describing a significant reduction in the occurrence of anomalies in diabetic women who underwent intensive metabolic regulation before the time of conception.[14] Thus there should be a good prognosis for the outcome of diabetic pregnancies.

In view of the improvements in medical care, obstetric management, and neonatal treatment that have occurred and are reflected in those recent reports, a question has been raised: do these classification systems still provide predictive value with regard to the outcome of diabetic pregnancies? This report examines the degree of attainment of this potential, as well as prognostic significance of White's classification and Pedersen's prognostically bad signs of pregnancy. Since Vanderbilt University Medical Center is a tertiary care referral center, the pregnancies delivered here represent a wide variety of clinical situations. Among the pregnancies described in this report the situations range from that of women who presented for metabolic regulation before the time of conception to women who presented for the first time at our center in diabetic ketoacidosis and with a fetus with intrauterine death.

Reassessment of our patient population by White's classification demonstrated that this classification continues to be of prognostic significance with regard to perinatal mortality. Similarly, Pedersen's prognostically bad signs were also found to continue to be of prognostic significance in the identification of diabetic pregnancies at risk for perinatal mortality. Of further interest, however, is the observation that the perinatal mortality was associated principally with one of three situations: fetal congenital anomalies, maternal neglectors, and women referred to our center late in their gestations with either maternal or fetal complications. Nevertheless, when our patient population as a whole is considered, each of these classification systems maintains its prognostic significance for the identification of perinatal mortality.

This report also identified an association between each classification system and the occurrence of neonatal pulmonary morbidity in infants. Among women with prognostically bad signs of pregnancy, respiratory distress in infants was twice as common as in those women without prognostically bad signs. Similarly, in

a comparison of these two groups, the incidence of hyaline membrane disease in the infants was three times greater. When pregnancies were grouped by White's classification, pulmonary morbidity in general was significantly correlated with advancing disease according to White's classification. There was also a trend for an increased incidence of hyaline membrane disease in association with advanced disease according to White's classification although this did not reach statistical significance. Although each of these latter relationships may have been related to the gestational age of delivery of the infants, it nevertheless establishes that women with a higher White's classification are at increased risk for having infants with respiratory difficulties.

With regard to other types of neonatal outcome, average birth weight by White's classification was least in the D + F + R group. The infants in the D + F + R group were also significantly less likely to have macrosomia (which is based on both the weight and gestational age at delivery). This may indicate a relative impairment in uteroplacental function in these women with advanced classes of diabetes as compared to groups Bg, B, and C. The explanation for the increased occurrence of polycythemia in infants of pregnancies without prognostically bad signs is unclear. Neither advanced White's classification nor prognostically bad signs were predictive of other types of neonatal morbidity.

In summary, this report has established the continued usefulness of both White's classification and Pedersen's prognostically bad signs of diabetic pregnancies in identifying diabetic pregnancies at risk for the occurrence of perinatal mortality. Each of these also appears to be predictive of the occurrence of neonatal respiratory difficulties.

Legal abortion mortality in the United States: 1972 to 1982

Hani K. Atrash, M.D., H. Trent MacKay, M.D., Nancy J. Binkin, M.D., and Carol J. R. Hogue, Ph.D.

Atlanta, Georgia

Between 1972 and 1982, 186 women died as a result of legal abortion in the United States. The overall death rate resulting from legal abortion dropped nearly fivefold, from 4.1 per 100,000 abortions in 1972 to 0.8 in 1982. Women who were older, black, of high parity, and had abortions at a later gestational age were at increased risk of death throughout the 11 years of surveillance. During this period, the death rate decreased for abortions at all stages of gestation; the greatest decrease was with abortions performed during the second trimester. For the entire interval, mortality rates were highest for abortions performed by hysterotomy or hysterectomy and lowest for abortions performed by curettage. Before 1977, the most common causes of abortion-related death were infection, hemorrhage, and general anesthesia complications, respectively. Thereafter, hemorrhage became the most common cause of abortion-related death, followed in number by general anesthesia complications. Our findings suggest that there has been a marked decrease in septic legal abortion deaths, but potentially preventable deaths from general anesthesia and hemorrhage remain an important concern. Use of general anesthetics during first-trimester abortions should be carefully reviewed. (Am J Obstet Gynecol 1987;156:605-12.)

Key words: Abortion, mortality, maternal mortality

In 1982, 11 women died as a result of legal abortion in the United States. This represented a 57% increase over the reported number of deaths in 1981 and a 56% increase in the death-to-case rate. In addition, several changes in the characteristics of women both obtaining and dying of legal abortion and in the causes of legal abortion–related deaths have been observed recently.[1] These observations prompted a review of all abortion-related deaths identified through the Centers for Disease Control's abortion mortality surveillance for the period 1972 to 1982.

In this review, we analyze temporal trends in abortion mortality and study the factors that place a woman at increased risk of dying from legal abortion. We also describe the change in the leading causes of death from legal abortion and the change in each risk factor's contribution to abortion mortality over a period of time.

Methods

Abortion-related deaths are identified by the CDC from a variety of sources including the National Center for Health Statistics, state health departments, reports from abortion facilities and medical personnel, state medical and hospital associations, and state maternal mortality review committees. Each reported death is thoroughly investigated by examination of medical records and coroners' reports and is categorized as legal, illegal, spontaneous, or non–abortion related. Abortion-related deaths are defined as deaths resulting from a direct complication of an abortion, an indirect complication caused by the chain of events initiated by the abortion, or an aggravation of a preexisting condition by the physiologic or psychological effects of the abortion. We defined legal abortion as an abortion performed by a licensed physician or someone acting under the supervision of a licensed physician.

We used data from the annual CDC abortion surveillance to provide denominators for the death-to-case rates.[1] Because all states do not report on each variable, we applied the percentage distribution for those variables on which we had information to the total number of reported abortions.

Because of the small number of abortion-related deaths, particularly in the demographic and medical subcategories, for the purposes of comparison we elected to aggregate the data into two temporal groups: deaths occurring from 1972 to 1976 and those occurring from 1977 to 1982.

To describe the risk of death following various abortion procedures, we used four categories of abortion procedures. Suction curettage, sharp curettage, and dilatation and evacuation procedures performed at ≤12 weeks' gestation were categorized as curettage procedures.[1] The second procedure category, dilatation and evacuation, included procedures in the first category that were done at ≥13 weeks' gestation. We aggregated all instillation procedures into a third group, and hys-

terotomy and hysterectomy procedures were combined to form a fourth group.

The relative risks and confidence intervals were calculated by the Mantel-Haenzel method as described by Rothman and Boice.[2]

Results

One hundred eighty-six legal abortion–related deaths were identified and investigated during 1972 to 1982. The legal abortion mortality rate has decreased steadily since 1972. Overall, the rate dropped 4.9-fold, from 4.1 per 100,000 procedures in 1972 to 0.8 per 100,000 procedures in 1982[1] (Fig. 1). In three instances (1977, 1979, and 1982) the number and rate of abortion deaths were higher than those of the immediately preceding year. For the composite years 1972 to 1976, the abortion mortality rate was 3.0 per 100,000 procedures, whereas for 1977 to 1982, the abortion mortality rate was 1.0 per 100,000 procedures.

Age. The risk of legal abortion–related mortality increased with age (Table I), but the magnitude of the risk decreased over the period of time. Between 1972 and 1976, women aged ≤19 years had a death-to-case rate of 1.9 per 100,000 in comparison with a death-to-case rate of 4.3 per 100,000 for women aged 30 to 44 years, giving a relative risk of 2.3. The comparable figures for 1977 and 1982 were 0.8 per 100,000 for women aged ≤19 years and 1.6 per 100,000 for women aged 30 to 44 years, giving a relative risk of 2.0 (Fig. 2). Women aged 20 to 29 years had an interme-

diate level of risk from 1972 to 1976, but in 1977 to 1982 they had virtually the same risk as women 19 years old or younger (Fig. 2).

Race. Women of black and other races had a higher risk of mortality than white women during both time periods (Fig. 3). Athough the magnitude of risk decreased for all races, the decline was greatest among whites. As a result, the relative risk for women of black and other races actually increased over the period of time (Fig. 3). From 1972 to 1976, the death-to-case rate for white women was 2.0 per 100,000, whereas for women of black and other races the rate was 5.3 per 100,000, yielding a relative risk of 2.6. From 1977 to 1982, the rate for white women was 0.6 per 100,000, whereas for women of black and other races the rate was 1.8 per 100,000, yielding a relative risk of 3.0.

Parity. The risk of mortality increased with increasing parity (Table I). This finding was observed for both time periods (Fig. 4), although the magnitude of risk decreased over the period of time. From 1972 to 1976, nulliparous women had a death-to-case rate of 2.4 per 100,000, whereas women with three or more previous births had a rate of 4.8 per 100,000, yielding a relative risk of 2.0. From 1977 to 1982, nulliparous women had a rate of 0.7 per 100,000 whereas women with three or more previous births had a rate of 2.3 per 100,000, yielding a relative risk of 3.3.

Gestational age. The risk of dying from legal abortion increased steadily with increasing gestation time. From 1972 to 1982, abortions performed at ≤8 gestational weeks carried the lowest rate of mortality—0.5 deaths per 100,000 procedures (Table I). In comparison, abortions performed at 9 to 10 weeks' gestation had a 2.2 times higher risk of death; the risk increased to 24.5 times at ≥21 gestational weeks (Table I). The risk of death increased with increasing gestation in both time periods, although with time the magnitude of risk in each gestational age group decreased (Fig. 5). The greatest decrease over the period of time occurred in the ≥21-week group (89%), followed by the 13- to 15-week group (74%), the 11- to 12-week group (67%), the 9- to 10-week group (59%), and the 16- to 20-week group (55%). The decrease in mortality risk for abortions performed at ≤8 gestational weeks was 33%.

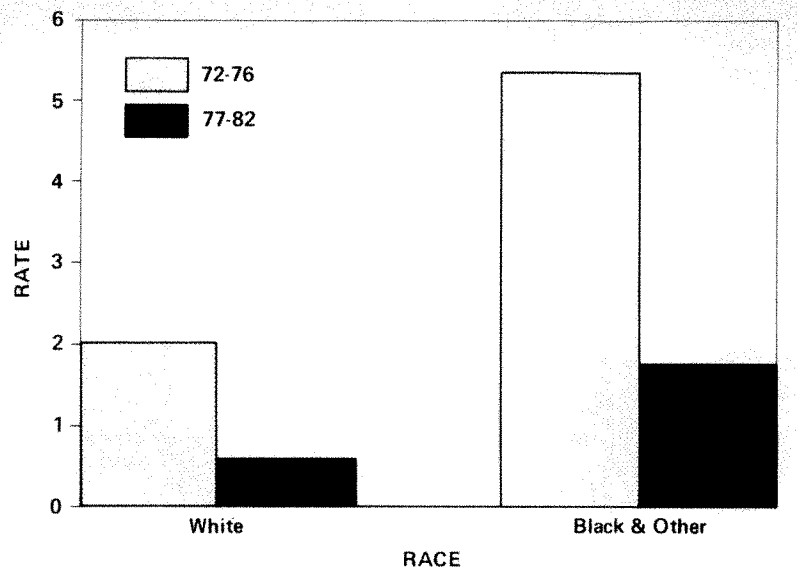

Fig. 3. Legal abortion mortality by race, United States, 1972 to 1976 and 1977 to 1982.

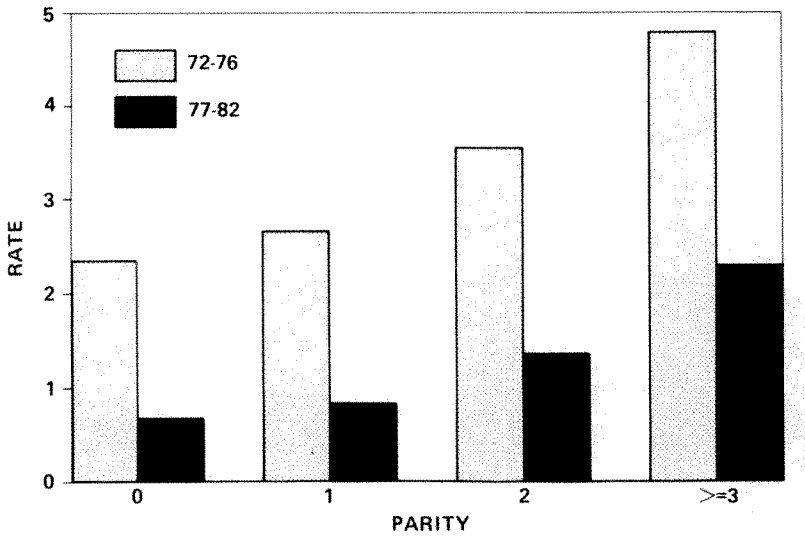

Fig. 4. Legal abortion mortality by parity, United States, 1972 to 1976 and 1977 to 1982.

Geographic region. Women obtaining abortions in the South had the highest death-to-case rate in both time periods. From 1972 to 1976, the lowest rate, 2.5 per 100,000 procedures, was found in the Northeast, whereas the rate in the South was 4.3 per 100,000 (relative risk = 1.7). From 1977 to 1982, the lowest rate, 0.4 per 100,000, was observed in the West, whereas the rate in the South was 1.3 per 100,000 (relative risk = 3.2). Although all geographic areas experienced a drop in abortion mortality over the period of time, the greatest drop (sixfold) occurred in the West (Fig. 6).

Method of abortion. In both time periods, the lowest mortality rates occurred with curettage abortion, whereas the highest rates occurred with hysterotomy and hysterectomy. Over the period of time, the mortality rates for all methods except hysterotomy and hysterectomy decreased. From 1972 to 1976, the death-to-case rate for curettage abortion was 1.3 per 100,000, whereas from 1977 to 1982, the rate was 0.6 per 100,000, a decrease of >50%. From 1972 to 1976, the rate for dilatation and evacuation was 8.5 per 100,000, dropping to 3.2 per 100,000 in 1977 to 1982, a decrease of 62%.

The greatest declines in abortion mortality over the period of time occurred with instillation methods. Saline instillation had a death-to-case rate of 17.8 per 100,000 from 1972 to 1976, whereas the rate fell to 5.1 per 100,000 from 1977 to 1982, a decrease of 71%. Prostaglandin and other instillation had a rate of 13.1

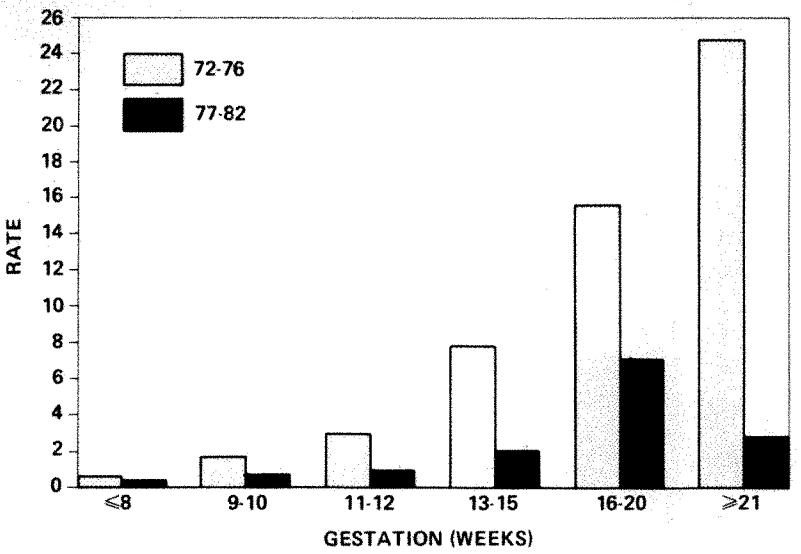

Fig. 5. Legal abortion mortality by gestation, United States, 1972 to 1976 and 1977 to 1982.

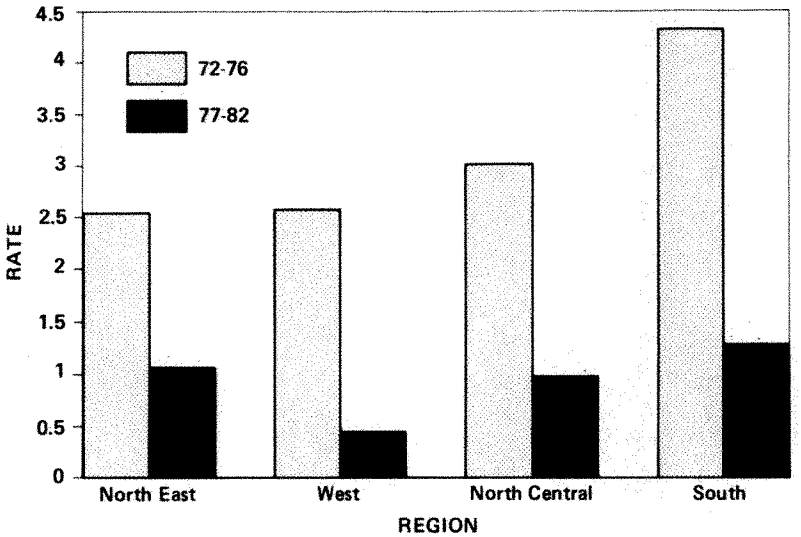

Fig. 6. Legal abortion mortality by region, United States, 1972 to 1976 and 1977 to 1982.

per 100,000 in 1972 to 1976, whereas the rate fell to 3.2 per 100,000 from 1977 to 1982, a decrease of 76%. By contrast, the death-to-case rate associated with abortion by hysterotomy and hysterectomy actually increased from 44.7 per 100,000 in 1972 to 1976 to 58.5 per 100,000 in 1977 to 1982. For all abortion procedures, the risk of death increased with increasing gestational age, and, for each gestational age, the risk of death was lowest for curettage abortion and highest for abortions done by hysterotomy and hysterectomy (Table II).

Causes of death. The leading causes of abortion-related deaths in both time periods were infection, hemorrhage, complications of general anesthesia, amniotic fluid embolism, and pulmonary embolism. Nevertheless, although the number of deaths due to each cause decreased over time, the proportion of deaths resulting from some causes decreased while the proportion due to other causes increased. The proportion of deaths from infections decreased from 26% in 1972 to 1976 to 13% in 1977 to 1982; the proportion resulting from amniotic fluid embolism decreased from 12% to 8%, and the proportion resulting from pulmonary embolism decreased from 11% to 7%. However, the proportion of deaths due to complications of general anesthesia rose from 8% in 1972 to 1976 to 18% in 1977 to 1982, and deaths due to hemorrhage rose from 12% in 1972 to 1976 to 23% in 1977 to 1982. As a result of these shifts, the most frequent cause of death during 1972 to 1976 was infection, followed in number by hemorrhage, amniotic fluid embolism, pulmonary embolism, and complications of general an-

Table II. Legal abortion–related deaths and mortality rates by gestational age and abortion procedure, 1972-1982

Procedure	*Gestataional age (wk)*						*Total*

‡Six cases done by other procedures and three cases with unknown gestation were excluded.

esthesia. In 1977 to 1982, the most frequent cause of death was hemorrhage, followed in number by complications of general anesthesia, infection, amniotic fluid embolism, and pulmonary embolism.

The leading causes of death varied by age, race, method, region, and gestational age. The racial and age differences, however, disappeared when we adjusted for method of abortion. For curettage abortions the leading cause of death during the 11-year study interval was complications of general anesthesia, whereas for dilatation and evacuation it was infection, for instillation procedures it was amniotic fluid embolism, and for hysterotomy and hysterectomy it was pulmonary embolism. For abortions done at ≤12 weeks' gestation, the leading cause of death was general anesthesia complications, and for abortions done at ≥13 weeks, infection was the leading cause of death. In the Northeast, the leading cause of abortion-related deaths was general anesthesia complications, whereas in the West, South, and North Central regions, the leading cause of death was infection.

Comment

Age, race, gestational age, and abortion method have been repeatedly identified as risk factors for legal abortion mortality and morbidity.[3-7] However, the risk associated with each of those variables has changed over a period of time. Although age has continued to be a determinant of legal abortion mortality, it clearly has become less important. The declining mortality risk among older women may be related to the improved management of infection and pulmonary embolism, the leading causes of death in the older age group between 1972 and 1976. These two causes of death have had the greatest decrease between the two time periods.

A portion of the difference in race-specific mortality may be explained by differences in the gestational age distribution between races. Women of black and other races have a smaller proportion of abortions performed at ≤8 weeks' gestation (the safest interval) and have a larger proportion of abortion at 11 to 12 weeks, as well as during the second trimester. In 1981 10.6% of white women obtaining legal abortions had the abortions during the second trimester, compared with 12.9% of black women and those of other races.[1] Age differences do not explain the mortality differences between the races because only very small differences in the age distribution between the race groups were found. (In 1981 60.9% of white women obtaining legal abortions were ≥20 years old versus 64.4% of black and other women.)[1] We are unable, however, to examine the effects of other factors such as socioeconomic status, parity, marital status, and access to medical care—factors known to be associated with increased mortality.

The effect of parity on abortion mortality may be confounded by age. However, we were unable to examine this because of the lack of denominator data. Nonetheless, the magnitude of the relative risk is much greater with parity than with age, suggesting that age is unlikely to explain the whole difference. The consistently greater mortality in the South may be caused in part by the higher proportion of black women and those of other races who undergo abortion in this region.[1] The differential rates of decline and the variation in the causes of death in the four regions may be related to differences in medical practices. For example, differential decline in the use of general anesthetics or more aggressive management of complications in certain regions could result in variable regional declines in mortality rates.

The very high death-to-case rate with hysterectomy or hysterotomy in comparison with that of other methods may be explained by both the probable higher risk status of women undergoing these procedures and the inherent risk of death from major surgical procedures.[8] The marked drop over a period of time in the mortality rates associated with curettage, dilatation and evacuation, and instillation procedures probably reflects an increase in operator skill resulting from postgraduate training and accumulated experience.

There have been major changes in the leading causes of abortion-related deaths over the time period studied.

These changes result from the changing characteristics of women obtaining legal abortion as well as changing medical practices. Mortality from infection may have declined because of improved treatment, including more aggressive evacuation of retained tissues from the uterus and more aggressive use of antibiotics. Deaths from pulmonary embolism may have declined, at least in part, because of improved infection treatments leading to a reduced likelihood of septic pelvic thrombophlebitis. In addition, improvements in the diagnosis and treatment of pulmonary embolism may have played a role in the decline.

The continued role of general anesthesia deaths in abortion mortality is of concern. In several studies, the use of general anesthesia for abortion, compared with the use of local anesthesia, has been demonstrated to result in both higher morbidity and mortality.[9, 10] Furthermore, it is possible that some of the deaths resulting from hemorrhage are indirectly related to general anesthesia use.[9-11]

Despite the increased risk associated with general anesthesia, its use has remained relatively common. The Alan Guttmacher Institute estimated that in 1982, more than 50% of legal abortions done in Northeastern clinics and physicians' offices (the region with the highest rates of general anesthesia–associated deaths) were performed in facilities offering only general or general and local anesthesia (personal communication). Although this percentage drops to 23.6 in the other three regions, the continued high levels of general anesthesia use is disturbing.

Gestational age was the most important patient-related variable associated with abortion mortality. There was more than a twentyfold difference in mortality between abortions performed at ≤8 weeks and those performed at 16 to 20 weeks. Gestational age was a much stronger predictor of mortality than age, race, parity, or region of the country. The importance of gestational age as a risk factor for mortality is consistent with findings in many studies on morbidity associated with abortion.[6, 7]

Although we cannot be certain that all legal abortion–related deaths from 1972 to 1982 were reported to the CDC, we believe that the use of multiple reporting sources decreases the likelihood that deaths are missed.[12] A study of maternal deaths in the United States between 1974 and 1978 relying on vital records only identified 141 abortion-related deaths, 63 of which were related to legal abortion.[13] In comparison, CDC's surveillance of abortion mortality identified 188 abortion-related deaths during the same period, 92 of which were related to legal abortion. This represents a 46% rise in legal abortion mortality case identification through CDC's surveillance system compared with vital records alone.

We used data from the annual CDC abortion surveillance to provide denominators for death-to-case rates. For most of the variables, denominator data were available for at least 75% of the total number of states reporting abortions. However, two variables, race (68%) and parity (52%), had smaller known denominators. It is unlikely that the characteristics of individuals in the groups for whom the information was reported differed markedly from those in groups for whom the information was not reported. Nevertheless, if such differences existed, they could influence our results.

Before 1978, only univariate data on the demographic characteristics of women obtaining abortions were available from our abortion surveillance. Bivariate data on the method of abortion and gestational age have been available since 1972 and were included in the analysis. Because we were unable to perform multivariate analysis with most of our variables, we cannot discount their potential interactions affecting the death-to-case rates. Nevertheless, we were able to determine the magnitude of risk for each variable and thereby estimate its relative importance.

In conclusion, legal abortion mortality has dropped dramatically over the past decade. The decline was more marked for older women, white women, and women obtaining abortion at later gestational ages. The leading causes of death have changed because of a differential in the rate of decline of various causes of death. Hemorrhage and general anesthesia complications have emerged as the leading causes of death and are of major concern. The increased morbidity and mortality associated with general anesthesia compared with local anesthesia have been repeatedly documented. The use of general anesthesia during the first trimester should be carefully reviewed. As with other surgical procedures, women having abortions should be counseled regarding the pros and cons of local and general anesthesia; use of local anesthesia should be encouraged. General anesthesia should be used only when appropriately trained staff and facilities for monitoring and resuscitation of patients are present. In addition, with the availability of intravenously administered fluids and blood products, it should be possible to prevent most legal abortion deaths caused by hemorrhage.

Successful pregnancy outcome after cervical dilation with multiple laminaria tents in preparation for second-trimester elective abortion: A report of two cases

Linda Van Le, M.D., and Philip D. Darney, M.D., M.Sc.
San Francisco, California

Two patients at 22 weeks' gestation underwent extensive cervical dilation with laminaria tents for elective abortion but continued their pregnancies instead. Both had normal deliveries. For the unusual patient who chooses not to carry out an abortion initiated with cervical dilation, successful pregnancy is possible and therapeutic intervention such as cervical cerclage seems inadvisable. (AM J OBSTET GYNECOL 1987; 156:612-3.)

Key words: Abortion, cervical dilation, pregnancy outcome

The decision to terminate a pregnancy is often difficult. The maximum gestational age at which termination is possible is determined by state law and institutional policy but usually does not extend beyond 24 weeks. Laminaria tents have been shown to be safe and effective for cervical dilation preceding second-trimester abortion by instrumental evacuation.[1] Two or three sets of multiple laminaria tents are used to achieve 2 to 3 cm of cervical dilation for abortions beyond 18 weeks' gestation.[2] Occasionally women who have decided to terminate a pregnancy change their minds after multiple laminaria tents have achieved considerable cervical dilation. Risks of infection or spontaneous abortion are unknown but are presumed to be high, perhaps without foundation.

From the Department of Obstetrics, Gynecology and Reproductive Sciences, University of California, San Francisco, and the San Francisco General Hospital.

Two patients who sought abortions at 22 weeks and subsequently changed their minds were followed up to uneventful delivery. In both cases many laminaria tents were placed in the cervix and later removed without complications. These two case histories provide some reassurance that normal pregnancy is possible for women who choose not to carry out an elective abortion already begun with laminaria insertion.

Case reports

Case 1. M. C., a 23-year-old woman, gravida, 4, para 1, elective abortions 2, was a heroin addict with unknown gestational age. She was incarcerated and desired termination of her pregnancy. Sonography showed a biparietal diameter consistent with 22 weeks' gestation. Six medium laminaria tents were placed, followed by six additional tents the next day. Metronidazole was given for trichomonal vaginitis; gonorrhea culture was negative. The patient was released from jail and, despite many urgent messages, refused to come to the clinic. Six days later she returned to explain that the laminaria tents were expelled on the third day. She denied having had passage of fluid from the va-

gina; the membranes were intact, and she had no fever or contractions. The temperature was 97.4° F, and the abdomen was nontender. No laminaria tents were seen and the cervix was long and closed. She still desired an abortion but failed to keep her next appointment.

At 37 weeks' gestation, with no prenatal care, she presented in labor and was rapidly delivered of a healthy 2790 gm female infant with Apgar scores of 8 and 8. Labor and the postpartum course were uncomplicated although the patient left against medical advice.

Case 2. B. M., a 27-year-old woman, gravida 6, para 3, spontaneous abortions 2, presented at 22 weeks' gestation with confirmation by sonography. She desired termination of her pregnancy because of the home situation. She had 17 small laminaria tents placed during the course of 2 days, but on the day of her scheduled abortion she requested that the laminaria be removed because she wished to continue the pregnancy. All the laminaria were removed; the membranes were intact. The cervix was 2 cm dilated and soft. There was no bleeding or fever, and sonographic evaluation showed cardiac motion and adequate amniotic fluid. She was given erythromycin, 500 mg three times a day orally for 7 days. The pregnancy continued without complication and at 40 weeks' gestation she was spontaneously delivered of a 3080 gm male infant with Apgar scores of 9 and 9.

Comment

Approximately 30,000 elective abortions requiring laminaria insertion for uterine evacuation were performed in 1981 according to the Centers for Disease Control. An unknown but probably very small proportion of these women (in our experience about one in 500) decide not to carry out the abortion after the laminaria tents have already been placed. The assumption has been that these pregnancies were in jeopardy because of a high risk of amnionitis and spontaneous abortion. There are, however, no data to support these negative assumptions or to guide clinicians regarding the treatment of patients who ask to have laminaria tents removed from the cervix. These two cases demonstrate that an adverse outcome is not inevitable.

Safe, rapid uterine evacuation for elective abortion in the latter second trimester requires 2 to 3 cm of cervical dilation. Since multiple laminaria tents remained in the cervix for 3 days in one case and 2 days in the other, this degree of dilation was achieved. A comparable spontaneous cervical change at 22 weeks in a desired pregnancy would be worrisome, but in both patients the cervix returned to normal within 1 week. Placement of a cervical cerclage would have been unwise. Prenatal care is especially important for these ambivalent patients. One patient sought care but the other did not.

Patients who decide not to end a pregnancy after having laminaria tents placed may be at higher risk for preterm labor and infection, but these did not occur in the two patients described here. Such vacillation about a critically important decision is fortunately a rare occurrence; after counseling the vast majority of women are firm in their decision to continue or not to continue a pregnancy and follow through accordingly. For the women who change their minds about abortion, removal of laminaria tents, consideration of antibiotic treatment, and referral for prenatal care seems the best course. Management should be expectant, and patients should receive documented warnings about the possibility of amnionitis and premature labor.

Long-term observations of cervical cancer

Axel N. Arneson, M.D., and Ming Shian Kao, M.D.
St. Louis, Missouri

A consecutive series of approximately 1100 patients, treated for cancer of the cervix over a span of 45 years, presents an increasingly favorable stage distribution. Emergence of exfoliative cytology as a diagnostic technique accelerates allocation of new patients to Stage I. Cumulative rates of dying from cervical cancer equate improved survival in terms of differences in prognosis and in effectiveness of treatment. Long-term observations bring into focus interval changes affecting the reservoir of individuals remaining at risk, which is maintained in accordance with rates of new patient inflow, as well as withdrawal for all categories of attrition. The several factors determining that balance, including age at diagnosis of cervical cancer, do not fall equally on all clinical stages. Age, a dominant factor determining incidence of second primary malignancies, may also have significance in unraveling the obscure etiology of corporeal malignancies evolving among patients irradiated in the treatment of cervical cancer. (AM J OBSTET GYNECOL 1987;156:614-25.)

Key words: Consecutive series of cervical cancer, long-term observations, early detection and survival, second primary malignancies, corporeal cancer in patients irradiated for cervical cancer

Adaptation of exfoliative cytology into gynecologic practice came as a direct outgrowth of the research of Papanicolaou in estrus of the guinea pig. On expanding investigation to include physiology of the human ovary, he detected malignant cells in vaginal secretions taken from some individuals. Despite that fact, however, his initial report in 1928 met indifferent success as a technique for early detection of cervical cancer.[1] Biopsy and tissue section of overt lesions remained the basis for diagnosis. Not until his report to the Commonwealth Fund in 1943 did the work gain interest and receive support.[2] His associates at the New York Hospital–Cornell Medical Center and the Harvard Group at Boston were among the earliest to initiate programs testing the method by clinical research.[3, 4]

An early consequence of the Papanicolaou test was more frequent detection of unsuspected cellular aberrations. Those encounters intensified interest in the then ongoing quest pursuing the morphologic transition of benign squamous cells of the cervix into precancerous and invasive forms of malignancy. The diverse spectrum of opinion, and the plethora of descriptive terms proposed by clinician and pathologist alike, prompted a "debate" presented as a special session at the 1952 annual meeting of the American Gynecological Society. The primary participants, Hertig and Younge[5] and McKelvey,[6] gave their material in sequence with each making final summation after the closing of open discussion. Proceedings at the session recalled Rubin's first two cases of "incipient cancer" described in 1910, Robert Meyer's prolonged attempt at tracing cellular development in individual patients, and the gradual ill repute falling on "precancerous" as a descriptive adjective. Hertig considered use of "precancerous anaplasia," a term describing the situation "more accurately etymologically speaking than does carcinoma in situ."

The Editorial Committee of the "Annual Report on Results of Treatment in Carcinoma of the Uterus and Vagina" adopted a system in 1950 that included preinvasive cervical cancer as Stage 0. They found usefulness of the category hindered by persistent difficulties in distinguishing dysplasia, carcinoma in situ, and early invasion. That situation prompted exclusion of the class in volumes 11, 12, and 13, but collection of data was resumed following the adoption of more definitive rules for stage grouping at the Vienna Congress of the International Federation of Gynecology and Obstetrics in 1961.[7] Data presented in the annual report included, for each collaborator, a graph showing interval changes in the proportion of patients allocated to the different clinical stages. Volume 15, collated for results obtained from 1954 through 1963, included data submitted by the earliest collaborators and is applicable to a span of 25 or more consecutive years. Despite variations in the experience reported by different institutions, there is evidence of a gradual increase in the proportional allocation of invasive lesions to Stage I. The trend of that

advance appeared to gain momentum after 1950, and thus coincided with the clinical adaptation of exfoliative cytology. That observation prompted us to extend an earlier report dealing with similar data in a consecutive series of private patients. It must be noted, however, that vagary in regional referral practice imposes a selective quality on any change in demography identified with a particular series of cases. There is, however, a measure of credence gained in this instance by the fact that all patients were treated at the same institution and were managed in consultation with the medical staff in attendance over the years in question.

Clinical material

A series of 384 consecutive cases of invasive cervical cancer, treated as private patients for the years 1935 through 1954, has been reported by Arneson and Williams.[8] Stage grouping was in accordance with rules adopted for the League of Nations system and included 10 examples of carcinoma in situ. The first such case was recorded for the year 1947. An additional 718 patients have been added to the series for the years 1955 through 1979. Stage grouping, made in accordance with the International Classification, has necessitated retrospective accommodation in the clinical staging of some cases classified in the earlier years of that period. Among 29 suspected of having early stromal invasion a review of tissue sections qualified 17 for Stage 1A and seven for 1B. The remaining five were transferred to Stage 0, resulting in a final ratio of 599 classified as invasive lesions and 119 as carcinoma in situ.

The allocation of patients into the different stages of tumor advance is shown in Table I for the two groups of consecutive cases. Evidence of earlier detection and diagnosis is made apparent for the 1955 through 1979 series by a significant increase in preinvasive forms and by a greater proportional allocation of invasive lesions to Stage I. The increase falling to Stage I imposes, by necessity, a compensatory decrease in assignment to more advanced forms. That effect appears here to fall largely on Stage II. The combined allocation to Stages I and II approximately 80% of all invasive lesions in each series.

Mean values given in Table I fail to demonstrate interval changes in stage distribution occurring over the time periods in question. Curves for the 1935 through 1954 report were derived by selecting determinate points on a biennial basis.[8] Points fixed at such

short intervals tend to widen fluctuations. A more linear quality is achieved for 1955 to 1979 by selecting points representing approximately equal numbers of patients. A composite graph is shown in Fig. 1. The first determinate point is taken at 1940 because of the small number of patients admitted into the series during early years of the 1935 through 1954 sequence. Declining numbers in the most recent years of the 1955 through 1979 series has been similarly treated by grouping data at year 1974. Explanation should be made for interruptions in curves illustrating stage distribution for years 1942 through 1945. Restrictions of that time not only precluded new admissions but also imposed losses in follow-up procedure. Additional comment on that failure will be given in discussions pertinent to the question.

The composite graph in Fig. 1 shows a sustained increase in the proportional allocation of patients to Stage I throughout the 45-year span, and as noted above, the combined numbers falling to Stages I and II total approximately 80% of all invasive lesions in each series. The graph includes an independent segment showing the proportional allocation to Stage 0. The number of such cases expands slowly following recognition of the first example in 1947. Incidence is elevated to a level near 20% by a more rapid accumulation beginning after year 1955. Concomitant with that increase, the allocation to Stage I appears to take on added momentum. An improved diagnostic technique might be expected to introduce an added flow of early lesions previously left undetected. By the same reasoning it should eventually reduce the reservoir of individuals who might otherwise, by delay and neglect, present more advanced disease at primary diagnosis. This is not made apparent here. If indeed there are inherent factors resisting attempts aimed at achieving earlier diagnosis, they obviously include differences in behavior of individual tumors that can prompt early dispersion or delay the onset of subjective symptoms.

Mention should be made of the "plateau" in preinvasive lesions that follows a rapid gain initiated in the year 1955. On reaching that level the added momentum imparted to the allocation of patients to Stage I appears to be slowed. This concerns the eventual relationship of these two events. If this be a valid epidemiologic observation, it suggests a point of saturation can be reached in the efficacy of exfoliative cytology as a diagnostic instrument. Advance beyond that point would seemingly depend on other methodology or a change in patient demography. This poses need for confirmation in a broader and more comprehensive spectrum of patients. Full significance of the contri-

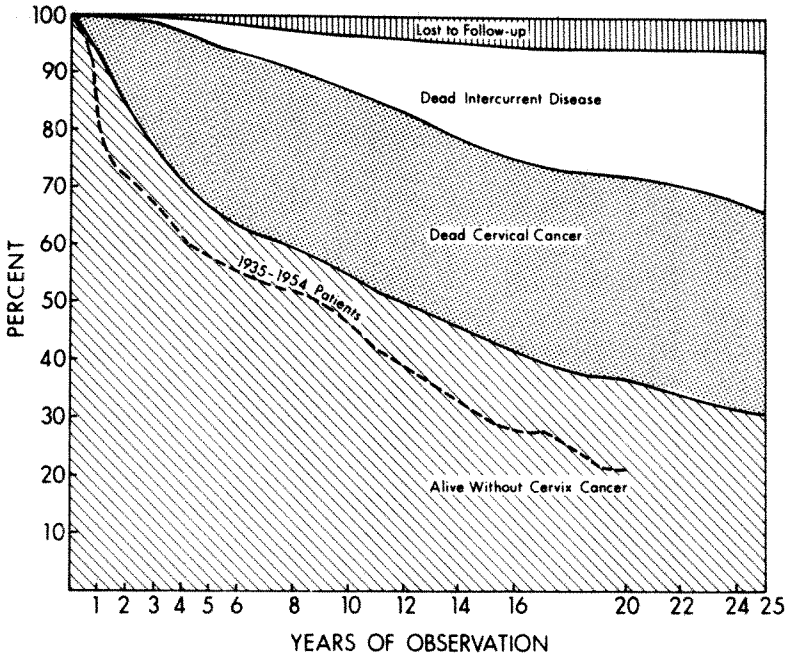

Fig. 2. Curves showing progressive encroachment made by different categories of attrition on the 1955 through 1979 reservoir of living patients. An additional curve presents 20-year cumulative survival for the 1935 through 1954 series.

bution made by exfoliative cytology to cancer diagnosis may never be precisely defined, but in the case of cervical lesions it holds a position of prime importance, enabling earlier detection that is shared only with research unraveling the morphologic transition of benign cells into malignancy.

Clinical results—invasive cancer

The primary treatment employed in both series of invasive cancers has usually been a combination of external irradiation with intracavitary or interstitial applications of radium. Before 1959 the external treatment was administered by 200 kV x rays. Cobalt 60 was used for a short period thereafter, but betatron therapy became the standard procedure after 1962. Exceptions in that management, made by use of primary surgical procedures, are more common in the 1955 through 1979 series.

Actuarial data for the 599 consecutive cases of invasive cancer treated since 1954 are given in Table II. Values show patient survival and specific categories of attrition including deaths resulting from cervical cancer or intercurrent disease, as well as deletions caused by failures in follow-up. In addition to those classified events the incidence of new primary cancers is shown as an independently derived set of values. Longevity is measured from the date of entry into the consecutive series. The point of beginning for patients referred with a confirmed diagnosis of cervical cancer is taken as the date of first examination under our observation. Patients under our observation before the detection of cervical cancer are entered into the series on the date of confirming biopsy. In the development of accumulative data an abstract was prepared for each patient showing follow-up status as of December 31, 1980. A death attributed to cervical cancer occurring 15 months after the point of beginning would find the patient recorded as alive and well at the end of 12 months' observation. On entering the following year at risk status, the patient would subsequently be withdrawn from observation and listed thereafter among other deaths attributed to cervical cancer. The same system is applied in recording attritions identified with either intercurrent disease or failure in follow-up procedure. In the case of deaths caused by cervical cancer, however, the method fails to recognize the time lapse between detection of persistent or recurrent disease, as well as its terminate state. An attempt to reckon with that deficiency was made in the 1935 through 1954 report by initiating an early withdrawal of suspect cases under the heading "alive or dead with cervic cancer."[8] The procedure qualified survival in "absolute" values but, by necessity, compacted cervical cancer deaths into an abnormally abbreviated time span that now presents problems in a direct comparison of clinical results.

Projecting cumulative data in Table II onto curves in Fig. 2 shows more distinctly the proportional encroachment made by different categories of attrition on the reservoir of living patients. Deaths resulting from cervical cancer dominate all events during the first

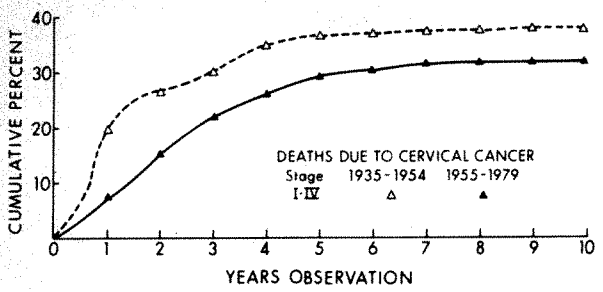

Fig. 3. Curves showing respective 10-year cumulative withdrawal for deaths resulting from cervical cancer in the 1935 through 1954 series and in the 1955 through 1979 series of patients with invasive disease.

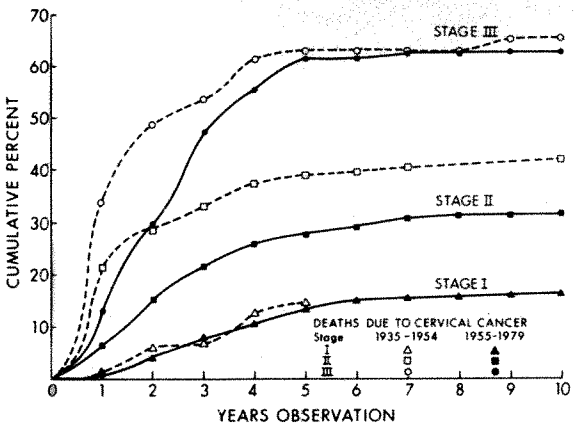

Fig. 4. Curves showing respective 10-year cumulative withdrawal for Stages I, II, and III seen in Table III.

5 years of posttreatment observation. Subsequent encroachment by that category is reduced sharply, however, and at time intervals greater than 10 years the proportional increase falls within two almost parallel curves. Deaths resulting from intercurrent disease, on the other hand, accumulate gradually during early years in follow-up but increase more rapidly as the dominance exercise by cervical cancer begins to fade. At long-term observations the relative proportion of deaths attributed to intercurrent disease may equal, or even exceed, that assigned to cervical cancer. The cumulative loss in follow-up for the 25-year span totals only 5.8%.

An additional curve included in Fig. 2 shows 20-year cumulative survival for the 1935 through 1954 series.[8] The initial rate of fall is exaggerated by the practice then followed in withdrawing patients on the detection of treatment failure. In other respects, however, the curve is seen to fall along a slope 8% to 9% below that for the more recent series until divergence develops near the tenth year of posttreatment observation. Irregularity beyond that point reflects indeterminancy in the long-term status of patients treated before the 1942 through 1945 void in follow-up procedure. That insufficiency precludes comparing long-term results largely affected by deaths resulting from intercurrent disease. Data applicable to the earlier years of posttreatment observations are made more stable by reinstatement of normal procedures in 1946 and by the effectiveness of follow-up during the 7-year period preceding the 1942 void. Since events dominating the period immediately following treatment are largely determined by deaths resulting from cervical cancer, an attempt should be made to reckon the improved survival noted for the 1955 through 1979 series in terms of advance in management or in more favorable curability introduced by an earlier detection of cervical cancer.

The 1935 through 1954 series records withdrawal of 143 examples as treatment failure, or 38.2% of the 374 patients with invasive cancer.[8] In the 1955 through 1979 series of 599 patients a total of 197, or only 32.9%, were withdrawn as cervical cancer deaths. The 5.3% difference suggests more effective management for the recent series. The rate of patient withdrawal, as measured by actuarial data, is tested in Fig. 3 for 10 years posttreatment observation. The curve for 1935 through 1954, as might be expected, shows a more rapid accumulation resulting from the withdrawal of patients on detection of evidence of treatment failure. After 2 years, however, it follows a slope in better conformity with that for 1955 through 1979 but remains at a level representing a greater rate in cumulative withdrawal. A review of these data by Sherry Breaux, M.P.H., of the Oncology Data Center shows the Yates corrected χ^2 equation to be statistically significant at the 0.5 level ($\chi^2 = 4.162$, df = 1, $p = 0.0413$). It should be noted, however, that additional withdrawals are recorded in both series at time intervals of >10 years after treatment. Only one such event is recorded for the 1935 through 1954 series, but as seen in Table II, there are nine additional cervical cancer deaths in the 1955 through 1979 period. Projection of the curves to include those additional examples does not alter their positional relationship but narrows the cumulative difference to only 3.8%. That level, which is lacking statistical significance, fails to fully interpret the difference in overall survival noted in Fig. 2 for the 1955 through 1979 patients.

A difference in overall survival is more effectively explored by reviewing results obtained in different stages of the disease. Actuarial data determined by treatment failures in 1935 through 1954 and by cervical cancer deaths in 1955 through 1979 are given in Table III for Stages I, II, and III. Stage IV is omitted because no patients of that category survived more than 5 years after primary treatment. The "compacting" effect of treatment failure, as a standard of measurement,

is made apparent for 1935 through 1954 patients. Both groups show an increase in withdrawal that is expected to occur with advance in cervical disease. Finally, the number of patients falling into each category is recorded, and Table III presents total withdrawal as a fraction of that value. A review of data for Stage I presents a small margin of difference in end results that perhaps favors the effectiveness of treatment administered the 120 patients of the 1935 through 1954 series. Stage III, on the other hand, presents an uncommon level of equality in the respective results. Only in Stage II is a significant difference to be noted. The margin of difference favoring the more recent series is 9.2 percentage points at 10 years posttreatment. At 18 years, including all cervical cancer deaths in the 1955 through 1979 series, the marginal difference is 7.2 percentage points.

In compliance with the earlier attempt to interpret differences in survival by comparing rates for patient withdrawal, the 10-year data from Table III have been projected on curves shown in Fig. 4. Those for Stage I appear almost superimposed, but for a span of only 5 years. Beyond that time interval the rate for 1955 through 1979 pursues a slow but modest rise. Curves for Stage III present a more expected pattern, which reaches a level of parity at 5 years that is maintained throughout the remaining period. Evidence suggesting a difference in the effectiveness of tumor control is apparent only in the case of Stage II. The rate of patient withdrawal in 1935 through 1954 exceeds that for 1955 through 1979 at all time levels. If there has been an improved survival attributable to treatment alone, the gain is seemingly confined to the intermediate stages of tumor advance. This may be attributable to the higher energies employed for external irradiation and to a more frequent interstitial use of radium during the 1955 through 1979 period. The fact remains, however, that the data at hand do not alone explain the overall gain in survival noted in Fig. 2. That advance is more adequately displayed by the significant increase in patients allotted to Stage I after year 1954.

The dominant factors responsible for an added inflow of more favorable clinical material stem from the emergence of exfoliative cytology as a diagnostic instrument and from the clinical expertise gained in unraveling the morphologic transition of benign squamous cells into malignancy. It is a fortuitous circumstance that temporal relationship of the two series of consecutive patients here in question happens to coincide with impact of those events on clinical practice.

Carcinoma in situ

Prognosis for carcinoma in situ differs from that for invasive cervical cancer because of its relative freedom from deaths resulting from the disease and because of the younger age of most patients. This prompts differences in management and in survival which preclude any attempt to blend the two in a single statement of

Table IV. Cumulative data for 119 consecutive patients treated for carcinoma in situ in the years 1955 through 1979

end results. In the 1955 through 1979 series of 119 patients a surgical procedure was selected as primary treatment for 93. The usual procedure was abdominal hysterectomy, unless amended to meet requirements for vaginal repair of pelvic supports. Five of the surgically treated patients were selected for management by conization alone. One of that number became pregnant at a later date and was delivered of a mature infant. The remaining patients, 26 in number, were treated by irradiation alone. Indications for selecting that procedure, usually consisting of a single application of intracavitary radium, were determined in accordance with the physical status of the individual in question. The stated age at primary diagnosis of carcinoma in situ fell within a range of 35 to 49 years in 72, or 60% of the 119 patients. Sixteen were younger than 35 years, and 31 were age 50 or older. Average age is 45.4 years in contrast with 51.3 years for the 599 patients with invasive cancer. Both values fall slightly above the corresponding levels prevailing in the 1935 through 1954 period.

Cumulative data provide an effective means for correlating clinical experience in each group. Table IV displays for carcinoma in situ the same categories explored in Table II for invasive cancers of the cervix. Differences in survival are explained by the absence of withdrawals in Stage 0 for deaths due to cervical disease. Since loss due to failures in observation is at a low level in each group, it is obvious that attrition for carcinomas in-situ is largely determined by deaths due to intercurrent disease. The younger age level prevailing for Stage 0 might be expected to less mortality in that category. That expectation is not met by the respective 25-year cumulative values of 28.8% and 27.8%. There is, however, a different rate of cumulative increase. This can be detected by comparing the respective values given in Tables II and IV. The rate of increase for the younger group in Stage 0 falls behind that for invasive cancers; however, at time intervals of 15 or more years after treatment this rate begins to increase and more rapidly expands the accumulation to a total near parity with that reached by older patients with invasive disease. This is in itself an age factor that can be related to the increase in average level imposed by each successive year in follow-up. That effect grows with years in observation and gradually lessens significance of any advantage gained by a difference in average age at diagnosis of the cervical lesion. Data pertinent to the

occurrence of new primary cancers present the same time relationship. The importance of advancing age is discussed in greater detail in the section dealing with the incidence of second primary malignancy.

Second primary cancers

Probability for encountering a second primary malignancy among patients treated for cancer of the cervix is obviously related to size of the sample and to life span of the survey. The aforementioned review of 718 patients admitted into the series for years 1953 through 1979 has yielded a total of 61 new primary cancers. Six examples of double primary malignancy were disqualified because onset of the additional lesion either antedated or appeared in concurrence with recognition of the cervical tumor. Fifty-three of the 61 new primary cancers evolved among the 599 patients treated for invasive disease of the cervix, and eight were detected in the smaller group of 119 carcinomas in situ. Actuarial data for the two categories, presented in the previously reviewed Tables II and IV, show a 25-year cumulative value of 12.2% for the invasive group and 11.0% for the preinvasive form.

The various types of malignancy encountered among the 61 new primary cancers and distribution of those classes into the different stages of cervical disease is presented in Table V. Variety in type, including dominance of colon and breast disease, does not differ from that expected for women of comparable age in the general population. There is, however, disparity in distribution of the more dominant forms that points up significance of the younger age level prevailing among carcinomas in situ. The 119 patients classified as Stage 0 represent approximately 15% of the entire series but only one of 16 colon cancers evolved in that category, as compared with four of the same number of breast lesions. Average age for Stage 0 falls within the range known to be at risk for mammary cancer but at a level below that identified with equal exposure to colonic and some other forms of malignancy. Disparity can likewise be seen in the number and distribution of new primary lesions occurring in the different stages of invasive cervical disease. Stage I includes 32 of the 61 examples. That density in occurrence falls, however, with each stage of tumor. The rate of decline appears to be in accord with the proportion of patients withdrawn as cervical cancer deaths and the consequent effect of those events on the number of individuals remaining at risk. It is apparent therefore that in addition to factors related to number, time, and age at diagnosis of the cervical tumor, the occurrence of new primary malignancies is affected by the proportional

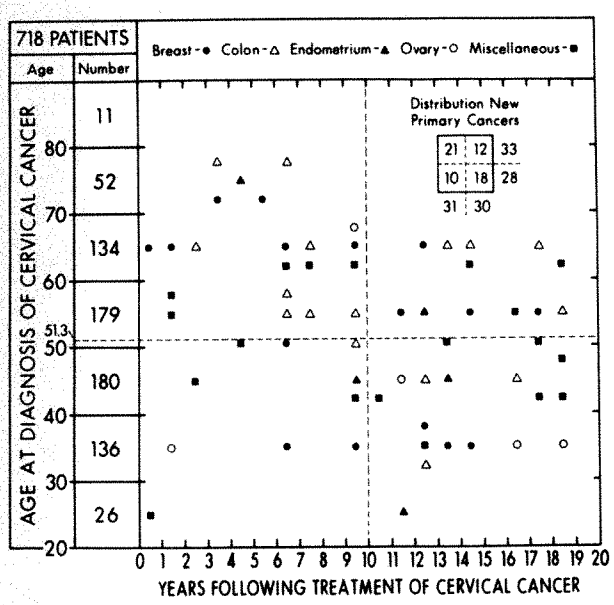

Fig. 5. Scattergram symbolizing posttreatment occurrence of new primary cancers among patients grouped according to age at diagnosis of the cervical lesion.

allocation of patients into the different stages of advance.

Before considering incidence of second primary cancers, mention should be made of two quandaries relevant to the gynecologic varieties that have been encountered. Vulvar lesions are strangely and unaccountably absent. The five endometrial forms evolved in tissues intensively irradiated in treatment of the cervical tumor, and two of them were nonepithelial in type. Rather than now diverting to an examination of the connotation implied by those relationships, we are deferring discussion of the potential for carcinogenic effect until a final summation of results.

An earlier report by Arneson and Schellhas,[9] for patients admitted into the series over years 1935 through 1967, derived incidence from cumulative data that were corrected to state more precisely the number at risk. Correction was made at the beginning of each successive year by subtracting one half of the number dying or withdrawn alive during that time interval. Values so determined tend to even out inequality in risk pattern. A total in "patient years" of observation was taken as the sum of all individuals presented in a state of risk for each time interval. Division of the number of new cancers by that total results in the incidence per patient year, which can then be related to the rate expected per 1000 patients. The more effective level in follow-up procedure, achieved for the 1955 through 1979 span, is believed to warrant deletion of the meticulous correction followed in the earlier report.

Data pertinent to the incidence of new primary cancers are presented in Table VI. Values given for each clinical stage include numerical size of the sample and average age at diagnosis of the cervical lesion. The number of new cancers detected in each category is seen to vary in accordance with size of the sample. Patient years of observation, presented as the total in numbers at risk for each successive time interval, show a similar relationship. It should be noted, however, that ratio of these totals to the numbers of patients in the sample is altered by differences in the rates of withdrawal for cervical cancer deaths. The relative freedom from such withdrawal, prevailing among cases of carcinoma in situ, results in a greater ratio of individuals remaining at risk. This can be expressed by the equation $1770 \div 119 = 14.87$. There are therefore approximately 15 patient years of observation for each individual classified in that category. Application of the same interpretation to different stages of invasive cervical cancer shows deterioration of the quotient to levels of 12, 10, and 6; magnitude of the increase in cumulative withdrawal can be seen in Table III. Among patients of the 1955 through 1979 series the rate is doubled for each stage of tumor advance.

Values representing cumulative percent of new primary cancers are not so precisely related to size of the respective sample. Those given for the different stages of invasive cervical disease are seen to fall in accordance with the rate of patient withdrawal for cervical cancer deaths and are easily correlated with the distribution of examples seen in Table V. The rate of 11.0% for Stage 0 should be compared with the 12.2% for all stages of invasive disease. Both represent the occurrence of such lesions among the number of individuals remaining at risk in each of the two distinct categories of cervical cancer. The eight examples occurring in Stage 0, detected in 1770 patient years of observation, yield the equation $8 \div 1770 = 0.00451$. The 53 examples occurring in all stages of invasive disease, detected in a total of 5982 patient years of observation, yield the equation $53 \div 5982 = 0.00885$.

The ratio of new cancers to the total in patient years of observation, as cited in examples given above, derives cancers per patient year that can be related to incidence expected in the general population. The rate 0.00451 obtained for carcinomas in situ is the lowest of all categories. The corresponding value for invasive lesions, as was determined in accordance with the total in patients remaining at risk, is found to be 0.00885. Incidence levels for the different stages of invasive disease will vary, however, in accordance with the effect of patient withdrawal on the totals in patient years of observation. Stage I, for example, undergoes the least attrition by deaths caused by cervical cancer and thereby presents a relatively greater reservoir of indi-

viduals remaining at risk. The occurrence of new primary cancers is consequently made more frequent, but differences in the reservoir prevailing in other stages can affect frequency as well as incidence. A decline in that reservoir might be expected to lower rates, but severe depletion, as noted for Stage III, may actually elevate incidence as determined for the small number remaining at risk. It should be pointed out, however, that average age of patients is seen to increase with each advance in tumor stage. That increase, perhaps indicative of time elapsing between onset of the lesion and its progression to the stage classed at primary diagnosis, could act to increase probability for encountering new primary cancers. It is a factor of significant importance.

The 61 new primary cancers detected among the 718 patients of the 1955 to 1979 series evolved in a total of 7752 patient years of observation. Incidence for the 25-year interval is 0.00786, or 786 examples to be expected per 100,000 population of comparable age and sex. Average age is found to be 51.3 years at diagnosis of the cervical lesion and 64 years at detection of a second malignancy. The results obtained in the 1938 through 1967 report are included in Table VI and present an incidence of 586 examples expected for 100,000 population. The lesser value for that time interval can be related to the greater burden in loss of follow-up data and to the younger age level prevailing in that period. Both factors would tend to limit the number of new cancers, as well as alter the ratio of that number to the total in patient years of observation. A factor of more positive relevance concerns a difference in the proportional allocation of patients to clinical Stage I.

Dominance of the age factor in determining incidence of second primary malignancies is displayed by the scattergram presented for the 1955 through 1979 series in Fig. 5. Patients are grouped according to the number falling into different age levels at diagnosis of the cervical lesion. The occurrence of second primary cancers is simulated by markers at specific time intervals after primary treatment. The chart is divided into four quadrants by two independently drawn lines. One, placed vertically to indicate a span of 10 years, divides the posttreatment period into two equal time intervals. A second line, drawn horizontally to indicate the 51.3 year level of average age, divides patients into two groups of almost equal numbers. Appropriate markers symbolize the occurrence of new primary cancers, and a small diagram included in the chart summarizes the number of examples detected in each quadrant. The time intervals in question show a yield of 31 second cancers for the decade immediately after primary treatment and 30 such lesions during the second 10-year plan. Distribution is not so precisely equalized at levels above and below average age. A total of 28 second primary cancers evolved among the 342 patients who were younger than the average, as compared with 33 examples detected among the 376 older individuals. The occurrence of new malignancies is lowest during the earlier years after treatment of the youngest patients. Density increases, however, as individuals of that category gain in age with each successive year. That sequence is altered among patients falling into the older age groups because further advance increases patient withdrawal by intercurrent disease. The scattergram indicates that the maximal density for the entire series occurs from the fifth through the fifteenth year after treatment. Possible exceptions to that rule fall in clinical Stages 0 and I, because of the younger age level prevailing in those categories, as well as the relatively greater reservoirs in patients remaining at risk.

The incidence of second primary lesions among patients treated for cancer of the cervix is a complex mechanism primarily determined by age at diagnosis of the cervical disease but also influenced by the proportional allocation of patients into the different stages of clinical advance and by the duration of the time interval in question.

Comment

Long-term observations offer a retrospective view of survival that more closely relates the effects of interval changes to fluctuations in the reservoir of individuals remaining at risk. It is not inappropriate to compare those events with a flowing stream feeding a reservoir or distributary, which maintains a balance determined by a ratio of inflow to that of a continuous drainage through efferent channels. Applying that concept to the particular change introduced at temporal conjuncture of the two groups here in question, conceives the effects of earlier detection and diagnosis as not only increasing the rate of inflow, but also lessening the rate of efferent loss by introducing a more curable pattern. The consequence is an expansion in volume of the "distributary," which reflects itself statistically by registering a proportional advance in survival. The concept can be similarly applied in appraising the average age of patients. All individuals entered into the distributary are subject to withdrawal at one time or another, but the potential does exist for some to remain at that state from the earliest years of the survey to its final closing. Surviving patients are grouped by age in each successive year. The 1935 through 1954 series, initiated by a low volume rate of inflow, expanded the reservoir at risk by a gradual increase in the addition of new patients. On the other hand, the 1955 through 1979 series begins with a reservoir functioning at a favorable level that is subsequently reduced by an eventual decline in

Table VII. Age distribution in two categories of uterine malignancy occurring at different intervals following treatment for cervical cancer

Histology	No. of patients	Age (yr)		Interval (yr)
		At cervical primary	At second primary	
Adenocarcinoma	5	56.6	68	11.4
Sarcomatous	4	34.7	55	20.3
Total	9	47	62.2	15.2
1955-1979	61	51.3	64	12.7

Data for 1955 through 1979 are included as a reference standard.

the number of new admissions. The consequence here is a difference in average age. The level for the first group is weighted toward the greater number of individuals admitted in concluding years of the series, whereas that for years 1955 through 1979 is weighted toward those who have been in the study longer. A difference in average was noted for the two groups in discussion of the significance of age as a factor determining incidence of new primary cancers. Whatever the importance of age, it is a factor found to vary in accordance with that prevailing at diagnosis of the cervical lesion, the number of years included in the survey, and specific categories of patient withdrawal which affect the reservoir of individuals remaining at risk.

Among 61 new primary cancers detected in the 25-year review of the 1955 to 1979 series, there are five examples of endometrial malignancy occurring 4 to 14 years after a program of irradiation applied in the treatment of invasive cancer of the cervix. That number of cases, presenting an incidence of 0.00083, appears to be in line with other histologic types recorded in Table V. It is the evolvement of such lesions in tissues so profoundly altered by postirradiation atrophy and sclerosis that is a point of concern. Two additional examples have been detected, but at time intervals beyond limits defined by this report. Both were diagnosed 22 years after treatment of a patient in 1961 and of another in 1963. Our first encounters with second primary cancers of this order occurred in the 1935 to 1954 series. A 69-year-old patient admitted in 1949 developed a Grade IV adenocarcinoma of the endometrium 8 years later. A young patient aged 30 years treated in 1947 presented with endometrial stromal sarcoma after an interval of 33 years.

These nine examples are grouped in an attempt to better define circumstances surrounding their origin. Stage distribution is in accordance with the proportional distribution of patients—six in Stage I; two in Stage II; and one in Stage III. The second primary lesions include five endometrial adenocarcinomas, two of which are poorly differentiated tumors and four are of a sarcomatous quality. In the more complex variety two have been diagnosed as mixed müllerian, one as carcinosarcoma, and one as an endometrial stromal sarcoma. This wide range in histology is associated with age distributions and with time intervals required for evolvement of new primary cancers, which differ from the average values established for the 61 examples detected in the 1955 to 1979 series. Among the five examples of adenocarcinoma of the endometrium, the stated age at diagnosis of the cervical lesion ranged from 43 to 72 years, with intervals between that diagnosis and detection of the second primary cancer ranging from 4 to 22 additional years. The four patients presenting with second lesions of a sarcomatous type are from a much younger age level and demonstrate a significant increase in interval years. Of that number the respective ages at diagnosis of the cervical tumor were 25, 30, 35, and 49 years. Intervals preceding evolvement of the second primary cancer ranged from 12 to 33 years.

Average values in age distribution at diagnosis of the first and second primary cancers are shown in Table VII for the two categories of endometrial disease. The difference in those values is taken as the interval in years. Corresponding data for 61 new primary cancers detected in the 1955 through 1979 series are included to serve as a reference standard. The five examples of diagnosed adenocarcinoma of the endometrium are in reasonably good accord with levels established for the larger sample. The slight decrease in interval years is adequately explained by the modest increase in average age at diagnosis of the cervical cancer. Values for the four second primary uterine cancers of a sarcomatous type deviate sharply from those given as a standard, with the difference noted chiefly in the much younger age level at diagnosis of the cervical primary. Average age at detection of the second primary is elevated to a more consistent level by a significant increase in interval years. The effects of that increase is also apparent in total averages for all nine examples of endometrial disease.

The circumstances here in question suggest a condition most apt to occur in patients younger than the average age expected for cervical cancer. The detection of sarcomatous types of lesions in tissues so long before exposure to high-dose levels of radiation points up the possibility for carcinogenic effects attributable to that

exposure. Repercussions of a malignant nature have been correlated with the exposure of young individuals to modest amounts of irradiation. More intensive therapeutic procedures, applied in the treatment of adults, have resulted in persistent dermal effects associated with malignant degeneration. The common denominator in such events may well be a prolonged interval between exposure and the eventual occurrence of a new malignancy. The issue is an interesting conjecture that should be pursued. Even if the hypothesis is proved to be correct, the low incidence so far noted is not one that would necessarily deprecate the usefulness of irradiation in the treatment of cervical cancer.

The value of endocervical curettage in the management of the patient with abnormal cervical cytologic findings

David A. Grainger, M.D., Daniel K. Roberts, M.D., Ph.D., Max M. Wells, M.D., and Douglas V. Horbelt, M.D., M.A.
Wichita, Kansas

Patients with adequate colposcopic examinations and dysplasia on the endocervical curettage specimen usually undergo further diagnostic evaluation. This study evaluated 712 patients and found the frequency of positive endocervical curettage specimens to be 17.6%. Cervical conization or hysterectomy specimens were examined in 66 cases with a positive endocervical curettage. Of these, 69.7% had histologic evidence of discontinuous dysplasia in the endocervical canal. The endocervical curettage specimens were grouped by the percentage of endocervical epithelium that was dysplastic: group 1, <10%; group 2, 10% to 50%; group 3, >50%. Confirmed histologic endocervical involvement was 80%, 56%, and 60%, respectively. The involvement of the endocervical canal also increased with increasing grade of cervical intraepithelial neoplasia. Of the 66 cases examined with positive endocervical curettage specimens, 62.1% had grade 3 cervical intraepithelial neoplasia on the ectocervix. Seven patients had positive endocervical margins, with six of these occurring in grade 3 cervical intraepithelial neoplasia lesions. Two unsuspected cases of cervical malignancy were identified by endocervical curettage. (AM J OBSTET GYNECOL 1987; 156:625-8.)

Key words: Endocervical curettage, abnormal cervical cytologic findings, cervical intraepithelial neoplasia

The management of the patient with abnormal cervical cytologic findings includes colposcopic examination of the cervix.[1-5] An adequate colposcopic examination is one in which (1) the entire transformation zone and the squamocolumnar junction are completely seen; (2) the entire extent of the lesion is seen; (3) the histologic, cytologic, and colposcopic impressions correlate within one grade; and (4) the endocervical curettage is negative for dysplastic cells.

An endocervical curettage is positive when dysplastic tissue is present. If failure to meet criteria 1, 2, or 3 is

Table I. Relationship between quantity of dysplasia in endocervical curettage specimens and disease in the endocervical canal

	Amount of dysplasia in endocervical curettage specimen (%)	*Patients with dysplasia in endocervical canal*	
		n	%
Group 1	<10	29/36	80
Group 2	10-50	14/25	56
Group 3	>50	3/5	60
Total		44/66	69.7

the reason for an inadequate colposcopic examination, the finding of dysplasia in the endocervical curettage is predictably high, with values ranging from 50% to 80%.[6] In adequate colposcopic examinations, the frequency of dysplasia in the endocervical curettage is reported to be betwen 8% and 18%.[7] Patients with positive endocervical curettage specimens and an otherwise adequate colposcopic examination are still at risk for the presence of neoplastic change in the endocervical canal. Evaluation of the endocervical canal may include conization of the cervix. The purpose of this study is to assess the correlation of a positive endocervical curettage with the presence of intraepithelial or invasive neoplastic disease in the endocervical canal.

Methods

Data were obtained for this study by reviewing the reports of colposcopic examinations performed at a university-affiliated colposcopy clinic from July 1982 through July 1984. During this 2-year period, clinicians trained and supervised in colposcopy by a gynecologic oncologist examined 838 patients to evaluate abnormal cervical cytologic findings. Pregnancy patients (96) and those with inadequate colposcopic visualization (30) did not undergo endocervical curettage and were excluded. Therefore 712 patients were available for analysis.

A total of 126 patients had an endocervical curettage that was considered positive, that is, one in which dysplastic tissue was present. A gynecologic pathologist reviewed all positive endocervical curettages for which surgical specimens were available (66/126). The amount of dysplastic tissue present in the endocervical curettage was divided into three groups: group 1 had <10% dysplasia in the endocervical specimen; group 2 had from 10% to 50%; group 3 had >50%.

Sixty-six cervical conization or hysterectomy specimens were reviewed for histologic diagnosis. The other 60 cases were performed at other institutions, and the specimens were not available for review. The endocervical canal and endocervical margin of each curettage, conization, and hysterectomy specimen were examined for the presence or absence of dysplasia. Endocervical canals that were denuded of epithelium were unevaluable and therefore considered to be negative. The final histologic grade of cervical intraepithelial neoplasia was correlated with the presence or absence of endocervical involvement.

Results

Evaluation was carried out for 712 patients with abnormal pap smears who underwent colposcopic examination. All cases had an endocervical curettage performed. Of these, 17.6% (126/712) had dysplasia present in the endocervical curettage. Of the 126 cases with a positive endocervical curettage, 66 surgical specimens of either conization or hysterectomy were available for review.

Table I shows the distribution of cases with respect to the quantity of dysplasia present in the endocervical curettage specimen. Group 1 consisted of 36 cases (63%) that had <10% dysplasia present in the specimen. Group 2 contained 25 patients (30%) who had dysplasia in between 10% and 50% of the specimen. Group 3 had five (6.6%) patients with >50% dysplasia.

Table I further depicts the relation between quantity of dysplasia and the presence or absence of endocervical dysplasia in the surgical specimen; 80% of group 1, 56% of group 2, and 60% of group 3 had dysplasia in the endocervical canal. Overall, 69.7% (46/66) of the patients with a positive endocervical curettage specimen had histologic evidence of dysplasia in the endocervical canal.

The presence of dysplasia in the endocervical canal directly correlates with the final histologic grade of cervical intraepithelial neoplasia on the ectocervix (Table II). Grade 3 cervical intraepithelial neoplasia was the final histologic diagnosis for 62.1% of those patients with a positive endocervical curettage specimen; grade 2 cervical intraepithelial neoplasia for 25.7%; and grade 1 cervical intraepithelial neoplasia for 9%. Table II also shows that 85% (6/7) of the cases with the positive endocervical margin occurred in those with grade 3 cervical intraepithelial neoplasia lesions.

Among the patients with a positive endocervical curettage for whom surgical specimens were available, two unsuspected cases of invasive carcinoma were identified. Neither patient had the diagnosis made by colposcopically directed cervical biopsy. Conizations prompted by a positive endocervical curettage revealed the invasive lesions. One patient had adenosquamous carcinoma, and the other had squamous cell carcinoma.

Comment

Evaluation by colposcopy of the patient with an abnormal cervical cytologic report places the burden of diagnosis on the colposcopist. If all patients with abnormal Papanicolaou smears underwent conization of

Table II. Correlation of histologic grade with positive endocervical curettage and endocervical margin

Final histologic grade	*Patients with dysplasia in endocervical curettage specimen (n = 66)*		*Endocervical canal positive for dysplasia*		*Positive endocervical margin*
	n	%	*n*	%	
Grade 1 cervical intraepithelial neoplasia	6	9	3/6	50	0
Grade 2 cervical intraepithelial neoplasia	17	25.7	12/17	70.6	1
Grade 3 cervical intraepithelial neoplasia	41	62.1	29/41	70.7	6
Invasive squamous cell carcinoma	2	3.3	2/2	100	NA*

*Not applicable.

the cervix, then the histologic interpretation would be all that is necessary to divide the patients who need further therapy from those who can be managed in a conservative fashion. However, not only is conization of the cervix a procedure that includes significant risk and expense, but it is also not practical to apply it as the first level of evaluation in all patients. The colposcopist's examintion produces an appropriate screen for cases that can be handled conservatively.

This series demonstrates the value of the endocervical curettage as a component of the colposcopic examination. First, it accurately reflects the presence of dysplastic epithelium in the endocervical canal, even when there is no other colposcopic evidence of involvement. In 69.7% of the cases with a positive endocervical curettage, discontinuous dysplasia was demonstrated to be present in the endocervical canal on the conization or hysterectomy specimen. Approximately 20% of specimens showed only denuded endocervical canals, which presumably were caused by the endocervical curettage. These were considered negative but may represent an even greater degree of correlation between endocervical curettage and the histology of the endocervical canal than we could confirm.

This study found a lack of correlation between the actual amount of dysplasia on an endocervical curettage specimen and its accuracy in predicting the presence of dysplastic epithelium. Our study clearly indicates that a small amount of dysplasia should evoke the same response as a large amount. Pathology reports that state "only a small amount of dysplasia noted on endocervical curettage" should not dissuade the practitioner from further evaluation of possible abnormalities in the endocervical canal.

In this study, two patients who met all the criteria for an adequate colposcopic examination except the presence of dysplasia on endocervical curettage specimen were found to have invasive carcinoma in the endocervical canal. These lesions would have been overlooked and allowed to progress had the endocervical curettage results not alerted the clinicians to the possibility of endocervical pathology. These cases represented 3.3% of the cases that were histologically and cytologically reviewed, which is slightly higher than others have reported.[7] This percentage may be statistically unusual; but even if the rate were half, it would still justify the use of the endocervical curettage. One recent large study identified 15 cases of invasive disease. Three of these had adequate colposcopic examinations except for dysplasia (two with grade 2 and one with grade 3 cervical intraepithelial neoplasia) in the endocervical canal.[8] These patients were found in an early stage of disease at a time when effective therapy could be used for cure rather than merely for palliation.

The value of the endocervical curettage in the colposcopic examination is therefore twofold. First, it accurately provides a statement concerning the involvement of the endocervical canal with dysplasia so that conservative therapies such as cryotherapy and laser can be used appropriately. Second, it provides a means for the identification of occult invasive lesions in the endocervical canal. Applied and responded to appropriately, the endocervical curettage should significantly decrease the rate of invasive processes erroneously diagnosed as intraepithelial. Therefore, unless it is clinically contraindicated, we recommend that endocervical curettage be a routine part of colposcopic evaluations for abnormal cytologic findings.

Atypia in cervical cytology as a risk factor for intraepithelial neoplasia

Joel S. Noumoff, M.D.
Philadelphia, Pennsylvania

All Papanicolaou smears obtained during the years 1977 to 1982 were reported by a descriptive cytologic interpretation instead of a numerical report. All smears showing "atypia" were reviewed and found to fall into one of three categories: inflammatory atypia, squamous atypia, and endocervical atypia. Patients with the latter two categories and those with persistent inflammatory atypia after specific therapy underwent colposcopy and directed biopsies if indicated. Colposcopically directed biopsies revealed that 29% of patients with atypical Papanicolaou smears had underlying cervical intraepithelial neoplasia. There was no statistically significant difference in the incidence of underlying cervical intraepithelial neoplasia among patients in each of the three categories of atypia. Of those with intraepithelial neoplasia, 35% had lesions of greater severity than grade 1 cervical intraepithelial neoplasia. We conclude that all patients with squamous, endocervical, and persistent inflammatory atypia on Papanicolaou smear should undergo colposcopic evaluation to rule out intraepithelial neoplasia. (AM J OBSTET GYNECOL 1987;156:628-31.)

Key words: Atypia, dysplasia, intraepithelial neoplasia, Papanicolaou smear

Since Papanicolaou[1] first described the use of exfoliative cytology for the detection of carcinoma, the role of cervical sampling in the routine screening for neoplasia of the uterine cervix has become recognized and well accepted throughout the world. In response to recent controversy regarding the use of Papanicolaou's original classification, the Terminology Committees of the American Society of Cytology and the International Academy of Cytology have recommended using a descriptive cytologic interpretation instead of a numerical report.[2]

Presently most cytopathologists report samples previously designated class II by using descriptive phrases that include the word atypia. Atypical smears are further subdivided into three categories: inflammatory atypia, squamous atypia, and endocervical atypia. The "atypical Papanicolaou smear" presents the gynecologist with a diagnostic dilemma. Although it does not indicate the presence of malignant cells, neither does it connote a normal state. At this time, some clinicians ignore the atypical smear, whereas others treat the patient with various antibacterial agents in the hope that the next cervical sample will be completely normal. It was therefore our decision to embark on a study to ascertain the clinical significance of cervical atypia reported from a Papanicolaou smear to help us to determine appropriate subsequent patient management.

Material and methods

For a 6-year period women with Papanicolaou smears reported as showing squamous or endocervical atypia or whose smears revealed persistent inflammatory atypia (8.7% of all the patients with inflammatory atypia) despite specific antivaginitis therapy (for example, for *Candida, Gardnerella,* or *Chlamydia*) were referred to the Dysplasia Clinic. During the time of this study, all Papanicolaou smears were obtained by moistened cotton-tipped applicators used to collect endocervical, exocervical, and vaginal pool samples. Each sample was directly smeared on a clean slide and immediately sprayed with fixative. After staining, the slides were screened by cytotechnologists and evaluated

for cellular adequacy. Abnormal slides were then reviewed by one of two cytopathologists.

At the Dysplasia Clinic a repeat Papanicolaou smear was obtained, and the cervix was then washed with a 3% acetic acid solution followed by colposcopic assessment of the epithelium by one of two colposcopists. An endocervical curettage was performed, and directed biopsies were obtained from areas of abnormality.

We define each of the three categories of atypia as follows. Inflammatory atypia includes morphologic changes of cells associated with specific infections, at times used in the same sense as repair (that is, reparative squamous epithelium in response to injury or ulcer, and so forth). In squamous atypia, the cytologic features are variable. The cells may be enlarged and may have an increased nuclear/cytoplasmic ratio and a minimally irregular nuclear membrane. At times the chromatin is smoothly granular and evenly dispersed but also may exhibit pyknosis. Binucleation is occasionally a feature. Chromocenters are at times numerous and sometimes single small nuclei may be noted. These cells are beyond the inflammatory atypia category previously described but do not meet the light microscopic criteria of the dysplastic (neoplastic) cell. Endocervical atypia includes abnormalities of glandular cells that may represent the glandular analogue of squamous atypia. Such changes are often associated with an endocervical polyp and endocervical hyperplasia, such as strikingly enlarged nuclei with numerous chromocenters and one or more large, conspicuous nuclei. Multinucleated endocervical cells may occur, and mitoses are not infrequent.

All of the charts from the Dysplasia Clinic of the Bellevue Hospital Center from 1977 through 1982 were reviewed. All patients with squamous, endocervical, or persistent inflammatory atypia were included in the study. Any woman with a previous history of cervical intraepithelial neoplasia or invasive cancer was excluded from the study. Patients who were pregnant at the time the atypical smear was obtained were excluded as were patients whose smears were positive for, or suggestive of, condylomatous or koilocytotic atypia. All abnormal slides were reevaluated for accuracy by a single cytopathologist before inclusion in this study. The data were tabulated and tested for statistical significance by χ^2 analysis.

Total	375	108	29

Results

A total of 67,260 cervical smears were done during the 6 years included in this study. The results are shown in Table I. From this patient population, after review of charts and pertinent Papanicolaou smear and biopsy slides, 375 patients evaluated in the Dysplasia Clinic for squamous, endocervical, or persistent inflammatory atypia were deemed suitable for inclusion in this study. The mean age of the patients with cervical atypia was 30.2 years. There was no significant age difference between patients whose cervical smears were grouped in each category of atypia.

Colposcopically directed biopsies revealed that 108 (29%) of the women with atypical Papanicolaou smears had underlying cervical intraepithelial neoplasia (Table II). The incidence of cervical intraepithelial neoplasia did not significantly differ between each of the atypia groups. The severity of the intraepithelial neoplasia did not differ significantly between the types of atypia with which the patients initially presented (Ta-

ble III). However, it is important to note that 38 (35%) of the 108 patients with intraepithelial neoplasia had lesions of greater severity than grade 1, and 17% had grade 3 (12 patients had severe dysplasia and six patients had carcinoma in situ). Analysis of the results tabulated from repeat Papanicolaou smears taken at the time of colposcopically directed cervical biopsies (Table IV) revealed that 92% of patients histologically demonstrated to have cervical intraepithelial neoplasia had cytologic classification as either negative (9%) or atypical (83%) on repeat smear. Conversely, only 2% of the patients with normal cervical biopsy findings were cytologically classified as having cervical intraepithelial neoplasia.

Comment

This study is the first to correlate atypical Papanicolaou smears with cervical biopsies guided by colposcopic direction. Our definition of atypia excludes dysplastic cytologic smears and those demonstrating any evidence of condylomatous or koilocytotic changes. The data suggest that patients with atypical smears (squamous, endocervical, or persistently inflammatory) are at high risk (29%) of having biopsy-verified cervical intraepithelial neoplasia, and the gravity of the disparity is demonstrated by our observation that 35% of the patients with cervical intraepithelial neoplasia had lesions of greater severity than grade 1.

The insensitivity of a Papanicolaou smear to diagnose cervical intraepithelial neoplasia in the presence of histologically verified cervical intraepithelial neoplasia is evident because 92% of the repeat smears from these patients were interpreted as negative or only atypical. Although the repeat smears in patients with biopsy-verified normal results suggest a high degree of specificity of the Papanicolaou smear technique, the overall accuracy of the method for the diagnosis of cervical intraepithelial neoplasia is encumbered by the formidable false negative rate seen in patients who were found on colposcopically directed biopsy to have cervical intraepithelial neoplasia. Perhaps our data provide an explanation for the previous report of Hulka[3] in which it was reported that 7.6% of patients with cervical atypia were ultimately found to harbor frank cervical carcinoma and provide a basis for the results reported by Nyirjesy[4] in which 75% of patients with persistently atypical smears were ultimately shown to have cervical intraepithelial neoplasia or invasive carcinoma on biopsy (not colposcopically directed).

The changes of early cervical neoplasia are a progressive continuum. Melamed and Flehinger[5] suggested that the atypical smear represents the mildest form of cervical intraepithelial neoplasia, and it is only the cytologic definition of mild dysplasia that has excluded it from consideration. The data presented here, however, do not support this, inasmuch as 10% of patients with atypical smears had cervical biopsies showing moderate dysplasia (5%), severe dysplasia (3%), and carcinoma in situ (2%).

We do not know why this rather inordinate number of patients with histologically verified intraepithelial neoplasia cytologically demonstrate atypia only. The adequacy of our technique for obtaining a representative cytologic sample was documented by critical cytologic screening, and our technique has been shown to be efficacious in several previous studies.[6,7] There

may exist a subset of patients with a distinct pathologic condition that results in this unusual constellation. This question may well be answered by our current study with the use of flow cytometry to quantify deoxyribonucleic acid to permit identification of a distinct population of such cells.

Our data indicate that all patients with squamous, endocervical, or persistent inflammatory atypia are at considerable risk of harboring an underlying intraepithelial neoplasia and that colposcopic evaluation is mandatory to significantly increase the diagnostic accuracy and to help differentiate patients with cancer precursors from those with nonneoplastic changes (Fig. 1).

I am indebted to Drs. Mitchell Morris, Silviu Kohan, Edward A. Weiner, and Geraldine Young for their contribution to this study.

Magnesium sulfate and ritodrine hydrochloride: A randomized comparison

David I. Hollander, M.D., David A. Nagey, M.D., Ph.D., and Marcos J. Pupkin, M.D.
Baltimore, Maryland

The efficacy of magnesium sulfate was analyzed in relation to ritodrine hydrochloride. Patients presenting in preterm labor between 20 and 35 weeks' gestation were prospectively randomized. Tocolysis was achieved for more than 72 hours in 35 of 40 cases (88%) where magnesium sulfate was administered and 31 of 39 cases (79%) in which ritodrine hydrochloride was infused. Delay of ≥7 days was achieved in 75% and 72% of cases, respectively. The mean dosage to achieve tocolysis was 4.5 gm/hr, in the magnesium sulfate group and 210.0 μg/hr in ritodrine hydrochloride–treated patients. The mean magnesium level to achieve tocolysis was 6.60 mg/dl. Side effects in the two groups were similar in number but less alarming in the magnesium sulfate group. Magnesium sulfate was found to be easy to administer and clinically efficacious. Its tocolytic action was found to be dose dependent and drug concentrations are easily determined. On the basis of this work and data from other investigators, magnesium sulfate should be used as the first line of tocolytic therapy with ritodrine hydrochloride as its pharmacologic backup. (AM J OBSTET GYNECOL 1987;156:631-7.)

Key words: Magnesium sulfate, ritodrine hydrochloride, premature labor

Prematurity and its prevention continue to be major problems for the obstetrician and the neonatologist. In spite of the availability of several pharmacologic agents and more aggressive management approaches, the incidence of preterm labor remains at 5% to 10% and prematurity accounts for the vast majority (66% to 75%) of neonatal morbidity and mortality.[1]

It would appear that the incidence of preterm delivery may be reduced only through a program of strong patient and physician education that constantly reminds all parties involved of the possible occurrence of preterm labor and of the advantages of early diagnosis and expeditious treatment.[2] Thus tocolytic agents are not a panacea for preterm birth[3]; however, when preventive methods do fail or when early diagnosis is made,

one must be fully prepared to inhibit the process through proper pharmacologic intervention.

Much work has been published concerning the available tocolytic regimens.[4-10] The relative efficacies of the drugs have been demonstrated to be similar; therefore potency may not be the major consideration. Instead the incidence and severity of adverse effects may be the deciding factor. Agents with high therapeutic-to-toxic ratios would appear most appropriate. β-Sympathomimetic agents, of which ritodrine hydrochloride is the only form approved by the Food and Drug Administration, and magnesium sulfate, an agent quite familiar to obstetricians, are the drugs that have attracted the widest recent attention for tocolysis. Direct studies comparing their clinical efficacies and adverse effects are limited.[10]

This prospective study evaluates the efficacy and adverse effects of ritodrine hydrochloride and magnesium sulfate as primary tocolytic agents in a controlled, randomized fashion.

Material and methods

Patients presenting to the University of Maryland Hospital delivery room between August 1, 1984, and December 31, 1985, with preterm uterine activity were evaluated. These patients were monitored electronically for uterine contractions. If uterine contractions at a rate of at least two in 10 minutes with a duration of a minimum of 30 seconds were noted with a coexistent change in results of cervical examination, during a period of at least 1 hour, the patient was diagnosed as being in preterm labor. Primigravid patients presenting with this pattern of uterine activity and in whom the initial pelvic examination demonstrated the cervix to be at least 2 cm dilated or 80% effaced were also included in this preterm labor group. Excluded from the study were those patients in premature labor with cervical dilation >4 cm, premature rupture of the membranes, or any other maternal or fetal condition necessitating delivery. Also exluded were patients with multiple gestation and those having gestational lengths of <20 or >35 weeks. Seventy patients met those criteria and were prospectively randomized to either ritodrine hydrochloride or magnesium sulfate for intravenous tocolysis during this time period. Randomization was generated through the use of random number tables with ritodrine hydrochloride being given for odd integers and magnesium sulfate with even integers.

All patients selected for study were given an intravenous infusion of 500 ml of 5% dextrose–0.45% sodium chloride during a period of 15 to 30 minutes during an observational period when history, physical examination, and baseline laboratory (complete blood count and serum electrolytes) and electrocardiographic tests were done. If uterine activity persisted and no contraindication to tocolysis was found, drug therapy was instituted.

Patients randomized to ritodrine hydrochloride therapy (group 1) were placed on a regimen of an initial dosage of 100 μg/min given as a constant intravenous infusion. This dosage was increased by 50 μg/min every 10 to 15 minutes until contractions ceased, a maximum of 350 μg/min was attained, or unacceptable maternal side effects developed. If tocolysis was successful, the infusion was maintained for 12 hours at the lowest effective dose to maintain uterine quiescence. Patients with failure to achieve tocolysis with intravenous ritodrine hydrochloride despite maximum drug dosages or who were unable to tolerate the medication because of adverse side effects were placed on the magnesium sulfate (group 2) regimen, and the ritodrine hydrochloride infusion was halted.

Magnesium sulfate was administered as a 4 gm bolus injection during a 20-minute period followed by an infusion of 2 gm/hr. The solution used was 40 gm of magnesium sulfate in 1000 ml of 5% dextrose in water. Dosage was increased by 1 gm/hr every 30 minutes until tocolysis was achieved or a serum magnesium concentration of 6 to 8 mg/dl was obtained. Magnesium levels were determined at 2, 6, and 12 hours during the intravenous infusion as well as each time the dosage was increased. After successful tocolysis, the infusion was decreased to the lowest effective rate to maintain effective tocolysis and to maintain serum magnesium concentrations in the range of 6 to 8 mg/dl. This management was then continued until a period of 12 hours without uterine activity was achieved. If contractions persisted despite therapeutic serum magnesium concentrations or if unacceptable adverse effects were encountered, the patients were placed in the ritodrine hydrochloride protocol as described above, and magnesium sulfate was discontinued. Patients with failure of both regimens had no further attempts at tocolysis.

In all patients, vital signs were closely monitored and recorded every 15 to 30 minutes during the initial 4 hours of infusion and then hourly. Accurate measurements of intake and urinary output were also made. Patients receiving ritodrine hydrochloride had serum potassium and glucose concentration monitoring at 6 and 12 hours into the infusion while magnesium sulfate–treated patients had deep tendon reflexes monitored every hour, with serum magnesium concentrations determined as above.

Oral tocolytic agents were administered to all patients beginning 30 minutes before discontinuation of the intravenous infusion. Ritodrine hydrochloride was administered at a dosage schedule of 10 mg orally every 2 hours for 24 hours, which was then reduced to 60 to 120 mg daily in divided doses (usually 10 mg orally every 4 hours). This was titrated to maintain a maternal

*No intergroup comparisons were statistically significant.

†Ritodrine hydrochloride was the first-line tocolytic in two cases; magnesium sulfate was the first in the other two.

pulse response of approximately 90 to 100 bpm. Some patients in both groups were placed on a regimen of oral terbutaline sulfate instead of ritodrine hydrochloride for maintenance therapy, 5 mg orally every 4 to 6 hours. Terbutaline was more often chosen for patients without third-party health care coverage because of its lower cost. No significant differences were noted in the use of either agent. Oral therapy was maintained until 37 completed gestational weeks. If premature labor recurred before 34 weeks with oral therapy, the patient was treated with the intravenous tocolytic regimen to which she was originally randomized. The protocol previously described was then adhered to in full.

Treatment success was defined by cessation of uterine activity and delay in delivery of ≥72 hours from the onset of tocolysis. In contrast, drug failure was defined as the inability to obtain cessation of uterine activity despite maximal dosages of ritodrine hydrochloride (350 mg/min) or, in the case of magnesium sulfate, serum magnesium levels considered therapeutic (6 to 8 mg/dl). These levels were maintained for a minimum of 30 minutes before discontinuation of therapy. The diagnosis of drug failure was also made when there was progression of cervical dilation to >4 cm, spontaneous membrane rupture, or significant maternal adverse effects that necessitated discontinuation of the medication involved in the judgment of the attending obstetrician.

Comparison of drug treatments was made with respect to maternal entrance data, cervical examination data, overall success rates, mean gestational age at delivery, total number of days gained in utero, and perinatal outcome. Adverse effects on mother and neonate were also compared. Statistical analysis with the Yates correction of the χ^2 test was performed to determine statistical significance ($p < 0.05$).

Results

Seventy patients were prospectively entered into the study protocol from August 1, 1984, to December 31, 1985. Thirty-six patients were randomized (via the random number table) to receive ritodrine hydrochloride as the first tocolytic agent prescribed. In the other 34 patients magnesium sulfate was administered first. Ritodrine hydrochloride was used an additional three times (total = 39) after failure to achieve tocolysis with magnesium sulfate. In contrast, magnesium sulfate was given in six additional cases (total = 40) when ritodrine hydrochloride was judged to be a drug failure.

Patients receiving single-agent treatment in either group or in whom both agents were used consecutively demonstrated no differences with respect to maternal age, parity, gestational age, or previous history of preterm deliveries (Table I). Results of pelvic examination on admission to the study in all groups were statistically equivalent (Table II). Statistical comparisons were made with respect to first-line therapy administered.

With respect to overall success (Table III), ritodrine hydrochloride was able to delay delivery 72 hours in 79% (31/39) of the patients to whom it was administered as either a primary or secondary agent. In 72% (28/39) of the instances of use of ritodrine hydrochloride, a delay to delivery of ≥7 days was attained. The success of ritodrine hydrochloride as a primary agent used to prevent preterm delivery for 72 hours was 83% (30/36 uses). Magnesium sulfate was able to delay delivery for 72 hours in 88% (35/40) of its uses (either primary or secondary) and for a period of at least 7 days in 75% (30/40) of uses. The efficacy of magnesium sulfate as a primary tocolytic agent in delaying delivery 72 hours was 91% (31/34 uses). Differences in the two treatment regimens, although favoring magnesium sulfate, did not demonstrate statistical significance.

A breakdown of drug failures (Table IV) after primary therapy with ritodrine hydrochloride (n = 6) demonstrates that in four of these cases (67%) magnesium sulfate was successful in delaying delivery at least 72 hours. In four of the ritodrine hydrochloride failures, a maximum dosage (350 μg/min) was attained without cessation of uterine activity, while in the other two cases maternal tachycardia of >140 bpm necessitated stoppage of the medication. In the two patients

who failed to respond to magnesium sulfate as well as ritodrine hydrochloride, one patient developed clinical and histologic evidence of abruptio placentae while the other patient developed a picture consistent with chorioamnionitis.

After drug failures with magnesium sulfate as the primary tocolytic agent, ritodrine hydrochloride was successful in delaying delivery 72 hours in only one of three cases (33%). Of the other two patients with failure to achieve tocolysis in either protocol, one was found to have evidence of abruptio placentae, and one was diagnosed subsequently as having chorioamnionitis.

Patients receiving ritodrine hydrochloride had cessation of uterine activity with a mean dosage of 210 μg/min. This level was reached in an average of 1.56 hours. Successful tocolysis with magnesium sulfate seemed dependent on reaching a serum concentration of not less than 5.6 mg/dl. The mean concentration of magnesium sulfate in the patients for whom this agent was successful was 6.6 mg/dl. Serum magnesium concentrations obtained during the infusion (Table V) demonstrate that progressive increases in the infusion rate of magnesium sulfate during a period of 3.3 hours to an infusion rate of 4.5 gm/hr were required to produce successful tocolysis. Although the time to cessation of labor was statistically shorter in the ritodrine hydrochloride group ($p < 0.05$), no cervical examination changes in the magnesium sulfate group were demonstrated during this same time period (when tocolysis was successful).

Neonatal data including birth weight, results of Dubowitz examination, and Apgar score were statistically equivalent when, as in Tables I and II, direct comparison of the two groups' successes and failures was made (Table VI). The four patients with failure of both regimens had poorer outcomes. Neonatal morbidity did not appear to be affected differently by either drug protocol.

Maternal adverse effects secondary to the medications involved, although different in presentation and severity, were comparable in number (Table VII). In two patients receiving ritodrine hydrochloride, as previously stated, maternal tachycardia necessitated discontinuation of the infusion. Similarly, metabolic changes in the patients receiving ritodrine hydrochloride were at times significant enough to suggest treatment (potassium <2.5 mEq/L). Other cardiovascular changes, although alarming to patient and staff, did not necessitate therapy. However, magnesium sulfate was found to produce increasing lethargy in two cases with diplopia as its major symptom, which required a decrease in the dosage infused to maintain serum magnesium levels in the therapeutic (6 to 8 mg/dl) range, yet without unacceptable side effects.

Comment

In this prospective randomized study, both ritodrine hydrochloride and magnesium sulfate were capable of delaying delivery at least 72 hours in 79% and 88% of their uses, respectively. Success, however, is not attained without adverse effects. Use of tocolytic agents must therefore be both judicious and cautious.

Ritodrine hydrochloride is a β-adrenergic agent with a preferential affinity for β_2-receptors. It was specifically designed and approved for use as a tocolytic agent.[4] Its mode of action is mediated through increases in adenyl cyclase, which in turn cause increases in in-

Table IV. Drug failures (n = 13)

*Both agents failed.

tracellular cyclic adenosine monophosphate. The effect of cyclic adenosine monophosphate on protein kinases in the cell membrane is to cause a decrease in intracellular calcium. This in turn inhibits smooth muscle contractility.

Clinical studies have favorably compared ritodrine hydrochloride with placebo as well as with other labor-inhibiting drugs. Wesselius-de Casparis et al.,[11] in an early prospective, randomized, placebo-controlled study, demonstrated the efficacy of ritodrine hydrochloride. Other work demonstrated ritodrine hydrochloride to be clinically superior to chlordiazepoxide[12] and ethanol.[13] Additionally, uncontrolled studies preceded the prospective, placebo-controlled clinical trials in this country permitting Food and Drug Administration approval.[4]

The clinical side effects reported for ritodrine hydrochloride are related to the α- and β-adrenergic effects of the drug. Maternal tachycardia, systolic blood pressure increase, and concomitant decrease in diastolic blood pressure are common effects. Chest pain or tightness, palpitations, electrocardiographic changes, and arrhythmias have been reported.[4] β-Adrenergic agents have also been implicated in the development of pulmonary edema, perhaps through augmentation of the normal pregnancy-related increases in plasma volume, fluid and salt retention, and decreases in total peripheral resistance, colloid osmotic pressure, and hematocrit. Metabolic effects associated with the usage of ritodrine hydrochloride include hyperinsulinemia, augmented glycogenolysis, and hyperglycemia. These changes may then produce increased lactate production and metabolic acidosis. In addition, potential side effects such as headaches, nervousness, nausea, and emesis as well as paralytic ileus have been reported. Despite its verified efficacy as a tocolytic agent, the high incidence of disturbing side effects has caused many to search for alternative therapies to ritodrine tocolysis.

Tocolytic properties of magnesium ions were first described in 1959 by Hall et al.,[14] who described prolongation of labor in patients treated with magnesium sulfate. The same investigators described its effects in in vitro isolated strips of uterine muscle. The mechanism of action of this ion has not been clearly elucidated but is most probably an antagonism to calcium ion binding to sarcoplasmic reticulum.

Table V. Magnesium sulfate levels

Infusion rate (gm/hr)	*Time of level (hr, mean)*	*Mean ± SD (mg/dl)*
2	1.0	4.09 ± 0.56
3	1.6	4.80 ± 0.61
4	2.7	5.74 ± 0.96
5	3.7	7.16 ± 0.32

Tocolysis achieved: Median infusion rate = 4.5 gm/hr at 3.3 hours (6.57 ± 0.80 mg/dl, mean ± SD).

Clinical studies of the efficacy of magnesium are abundant. Steer and Petrie,[15] in 1977, first published (in this country) a comparative study of magnesium sulfate and ethanol. They were able to demonstrate an improvement in successful preterm labor treatment with magnesium dependent on an early institution of therapy. Harbert et al.[16] demonstrated a reduction of uterine activity in patients with preeclampsia with serum magnesium levels of 5 to 8 mg/dl. In the preterm labor patient being treated with magnesium sulfate as the tocolytic agent of choice, Petrie[5] reported an 80% success rate in patients receiving continuous intravenous infusions of magnesium. Nochimson et al.,[6] using a similar protocol, were able to delay delivery 24 hours in 80% of patients. More recently Spisso et al.[7] as well as Elliot[8] have also established the clinical efficacy of this salt while studies directly comparing magnesium to β-adrenergic receptor agonists have shown no difference in efficacy.

The adverse effects of hypermagnesemia include impaired deep tendon reflexes, decreased muscle tone (for instance, diplopia), decreased respirations, cardiac arrythmias, and possible respiratory and cardiac arrest.

Table VI. Neonatal data* (n = 70)

	n	Birth weight (gm)	Dubowitz examination (wk)	Agpar score

Hyperglycemia (>250 mg/dl)	2
Magnesium sulfate (n = 33)	
Lethargy†	15
Nausea	7
Dry mouth	7
Dizziness	3
Nystagmus	1

*Necessitating stoppage of infusion in two cases.
†Necessitating decrease of dosage.

Adverse effects may be minimized by monitoring urinary output and clinical parameters. It should be stated that significant lethargy due to the action of ionized magnesium on the neuromuscular junction and striated muscle is frequent. Nausea, emesis, chest tightness, and pulmonary edema have also been reported.[8] Hypocalcemia has been the only metabolic change noted, and cardiovascular changes including transient hypotension, peripheral vasodilatation, and increased in stroke volume have been reported.

In the present study, magnesium sulfate demonstrated comparable clinical efficacy in direct comparison with ritodrine hydrochloride. The protocol for ritodrine hydrochloride in this study is identical to that of previous work published. Our administration algorithm for magnesium sulfate differs from those previously reported.[5-8] Serum magnesium levels of 5.8 to 7.5 mg/dl were needed to achieve adequate tocolysis. The data correlate well with results by Elliot.[8] It was possible to achieve these high concentrations by increasing the infusion to a rate of between 4 and 5 gm/hr during a period of 3 to 4 hours. This would appear to be an alternative approach to that of Spisso et al.,[7] who recommend an initial infusion rate of 8.4 gm in the first hour followed by 4.8 gm in the second hour and then a continuous effusion of 2.4 gm/hr. With either regimen, it appears clear that one needs to increase the concentration of magnesium ion in the serum to adequate levels to ensure the proper action and efficacy of this tocolytic agent. Since completion of this study, we have had success with a regimen that begins with a 4 gm bolus (during a 20-minute period), followed by a rate of 4 gm/hr, with increases to 4.5 or 5 gm/hr at 30-minute intervals, if needed. That the preterm labor patient is near the zenith with respect to plasma volume as well as glomerular filtration rate suggests the need for an increased infusion rate of magnesium sulfate necessary to achieve the high serum levels required for tocolysis.

In both the ritodrine hydrochloride and magnesium sulfate groups, oral β-sympathomimetics to continue prevention of preterm delivery as suggested by Brown and Tejani[17] were used. The two groups demonstrated an equal number of recurrences (two) of preterm labor with this protocol. This relative success is in agreement with the work by Spisso et al.,[7] who demonstrated the advantages of oral β-sympathomimetic therapy (on an outpatient basis) in a group receiving parenteral magnesium sulfate. Therefore the use of intravenous magnesium sulfate to achieve short-term tocolysis followed by an oral β-adrenergic receptor agonist, whether the drug of choice be ritodrine hydrochloride or terbutaline sulfate, to minimize recurrences appears successful and warranted as is the case for the use of magnesium sulfate after intravenous β-sympathomimetics.

Adverse effects appeared with equal frequency in the two groups; however, they were more alarming in nature in the ritodrine hydrochloride group. Unlike the adverse side effects seen with magnesium sulfate, ritodrine hydrochloride effects do not appear dose related but may be a phenomenon of receptor number and activity. This further limits the predictability of its action.

The present study further demonstrated the safety and efficacy of magnesium sulfate at high infusion rates within set therapeutic levels, which are easily obtained

and measured. It is this measurability of a serum response to therapy and a close relationship between that response and therapeutic success that allow physicians an end point with which they may gauge their therapy other than by maximum allowable dosage or by the development of intolerable adverse effects. Infusions of magnesium sulfate may be titrated to a serum concentration that seems from limited experience to be equivalent in all patients. If tocolysis is not achieved at that concentration, then preliminary data suggest that ritodrine may not succeed where magnesium has failed. The data (Table IV) demonstrate that in four of five patients in whom therapy with magnesium sulfate failed to achieve tocolysis, this failure was indeed in the patients' best interest. Although numbers are limited, a similar conclusion could not be reached in ritodrine hydrochloride failures. Some caution should be exercised in case more experience reveals greater risks of magnesium sulfate tocolysis than found in this study.

The perfect answer to the prevention of preterm delivery is probably not drug therapy. No drug is effective under all conditions and side effects are frequent. However, the efficacy of magnesium sulfate and its apparent safety appear to place this agent at the forefront of those therapies available for tocolysis. On the basis of our work and the articles of Spisso et al.,[7] Elliot,[8] and Harbert et al.,[16] it appears that magnesium sulfate appears to be the first-line tocolytic agent of choice in the treatment of premature labor. Our physicians and nurses were quite receptive to the use of magnesium sulfate as the result of their familiarity with its administration and side effects albeit at lower infusion rates. The drug appears to offer a high therapeutic-to-toxic ratio with a serum concentration response that is easy to determine.

Treatment of acute intrapartum fetal distress by β_2-sympathomimetics

C. Mendez-Bauer, M.D., Ph.D., Afrasiab Shekarloo, M.D., Vernon Cook, M.D., and Uwe Freese, M.D.

Chicago, Illinois, Madrid, Spain, and Montevideo, Uruguay

Patients with a diagnosis of severe intrapartum fetal distress by fetal heart rate and capillary blood pH monitoring received β_2-sympathomimetics to inhibit uterine contractions (tocolysis) while the obstetric team was preparing to deliver the fetus. Fetal heart rate and acidosis significantly improved after tocolysis; these fetuses were subsequently delivered in very good metabolic and clinical condition. The favorable effect of tocolysis on fetal homeostasis is attributed to the suppression of the ischemic effect of contractions on the placental circulation. The few fetuses having an extremely compromised placental function showed no improvement in heart rate or acidosis with tocolysis and were immediately delivered. Considering the mild side effects observed, the lack of maternal complications, and the remarkable perinatal outcome obtained, we recommend using tocolysis before delivering distressed fetuses. (Am J Obstet Gynecol 1987;156:638-42.)

Key words: Fetal distress, fetal resuscitation, tocolysis, fetal treatment

Intrapartum fetal distress is, in essence, a consequence of critically diminished fetomaternal exchanges often resulting from the ischemic effect of uterine contractions on the intervillous space (and sometimes also on the umbilical circulation) acting on an already compromised maternal placental circulation.[1] The prevailing treatment of this complication is an emergency delivery and the outcome is frequently an acidotic and depressed newborn infant.

When drugs able to effectively inhibit uterine contractions (tocolysis) became available,[2] we proposed using them to treat intrapartum fetal distress.[3] The rationale for their effect is to remove the aggravating influence of uterine contractions and hence enable the improvement of the fetal metabolic condition. Encouraging results based on a few observations were reported with this method; that is, nonacidotic and vigorous newborn infants were delivered in spite of having had serious fetal distress sometime before delivery.[3]

Subsequently, favorable results[4-9] and a small incidence of maternal and fetal side effects or complications[5, 7, 10-15] were reported with the use of tocolysis to treat intrapartum fetal distress. However, this method is not currently used in the United States, perhaps because a still larger clinical experience is needed before it will be adopted. In this study we describe our experience with the use of β_2-sympathomimetics in the treatment of fetal distress in 49 well-documented patients.

Material and methods

The observations included in this study were obtained from three different Perinatal Centers (Department of Obstetrics, Cook County Hospital, Chicago, Illinois; Maternity Santa Cristina, Madrid, Spain, and Service of Obstetrical Physiology, Montevideo, Uruguay) and the patients were managed basically according to the same protocol. High-risk patients were routinely monitored during labor regarding fetal heart rate, uterine contractility, and fetal capillary blood pH. Additional fetal samples were obtained within 30 to 60 minutes when consistent late decelerations, a severe cord compression pattern, or sustained bradycardia was recorded. In 49 of these patients, the diagnosis of fetal distress was confirmed when an actual fetal pH <7.20 or a descent >0.10 pH unit was found. Immediately afterward and while the obstetric team was preparing to deliver the fetus, a β_2-sympathomimetic was administered to the mother. The cervical dilatation at this time ranged from 2 to 10 cm (mode 4 to 6 cm). General infection, severe preeclampsia, cardiovascular disease, and hyperthyroidism were considered contraindications to the use of β_2-sympathomimetics.

Three different tocolytic drugs were studied: ritodrine hydrochloride (Yutopar, Prepar), orciprenaline (Alupent), and terbutaline. Ritodrine and orciprenaline were administered in a continuous intravenous infusion at doses of 200 to 350 and 20 to 30 μg/min, respectively. The dose was adjusted to inhibit uterine contractions

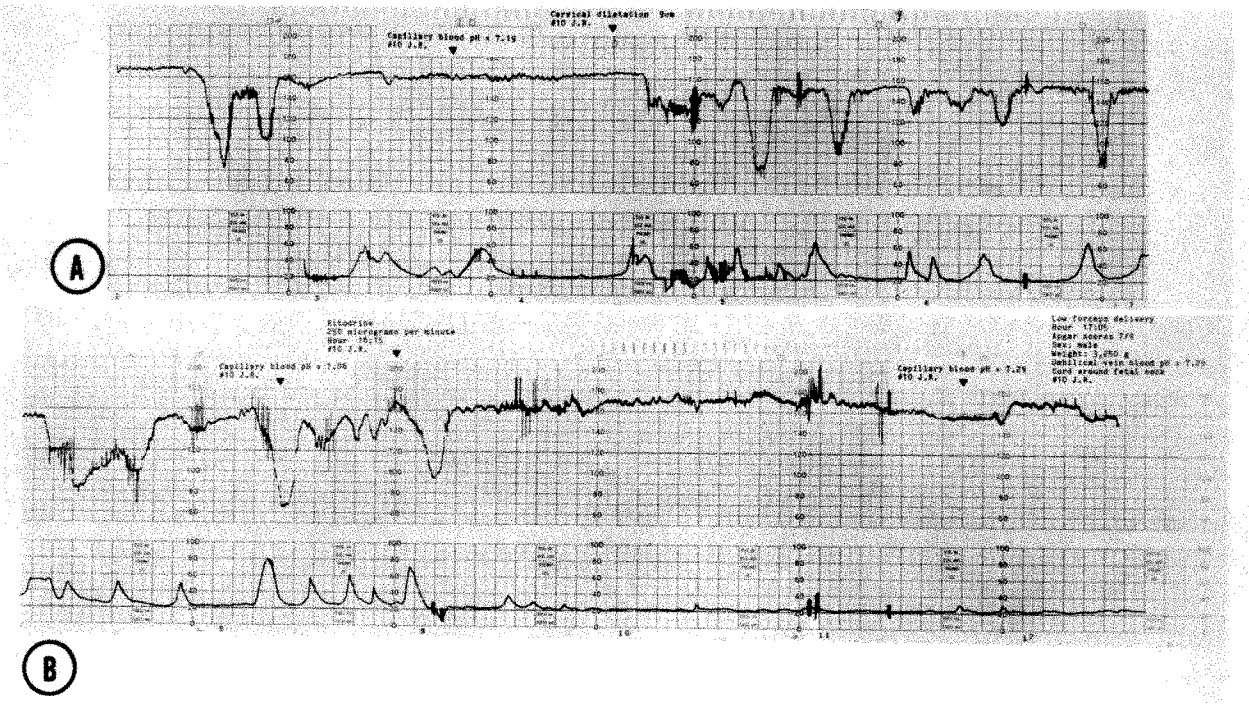

Fig. 1. Typical effect of β_2-sympathomimetics. A fetus with a capillary blood pH of 7.19 developed a severe cord compression pattern *(top)* and in 45 minutes the fetal pH fell from 7.19 *(A)* to 7.06 *(B)*. Six minutes later, after a ritodrine infusion was started, the fetal heart rate improved, after the disappearance of uterine contractions *(B)*. A fetal sample obtained 28 minutes after the onset of tocolysis shows a fetal pH of 7.29. The infant was delivered 22 minutes later by forceps. Apgar socres were 7 and 9. Umbilical vein blood pH was 7.29. The umbilical cord was wound around the fetal neck. Paper speed = 1 cm/min.

with minimal side effects. The duration of the infusion was 20 to 70 minutes (mode 20 to 30 minutes). Terbutaline was used as a single intravenous bolus injection of 0.25 mg. Twenty-five patients received ritodrine, 14 orciprenaline, and the remaining 10 terbutaline; no other therapeutic measure was used.

When the fetal heart rate showed a rapid improvement, that is, the late or variable decelerations markedly diminished in amplitude or totally disappeared or bradycardia reversed to a normal baseline level, the blood sampling was repeated within 10 to 20 minutes. If the fetal pH improved, the fetus was allowed to remain in utero until reaching a pH of $\geq$7.25 before being delivered. If no improvement occurred in the fetal heart rate or if the improvement was not accompanied by an increase in fetal pH, the fetus was immediately delivered.

Maternal age ranged from 15 to 39 years (mean = 24.0; SD = 6.4) and gestational age from 34 to 43 weeks of amenorrhea (mean = 39.8; SD = 2.12). The mean neonatal weight was 3167 gm (SD = 532.89). pH of umbilical venous blood, Apgar scores at the first and fifth minutes, neonatal body weight, maternal arterial pressure, and pulse rate were also recorded.

The data of the 37 fetuses who had successful sampling before, during, and after fetal distress were analyzed by a repeated measures analysis of variance. To determine which pairs of means were significantly different, the conditions were compared with a paired Student's *t* test.

Table I. Values of fetal blood pH (all samples included)

	pH		
	Mean	*SD*	*n*
Before distress	7.266	0.045	39
During distress	7.121	0.048	49
After β_2-sympathomimetics	7.239	0.073	44
Umbilical vein	7.256	0.072	47

Results

Except when otherwise stated, no significant differences ($p > 0.05$) were identified among the three β_2-sympathomimetic drugs used. A typical observation on the effect of tocolysis on fetal heart rate and pH is shown in Fig. 1 (*A* and *B*). The values of fetal blood pH are summarized in Table I. As fetal distress developed, the mean fetal pH decreased from 7.266 to 7.121

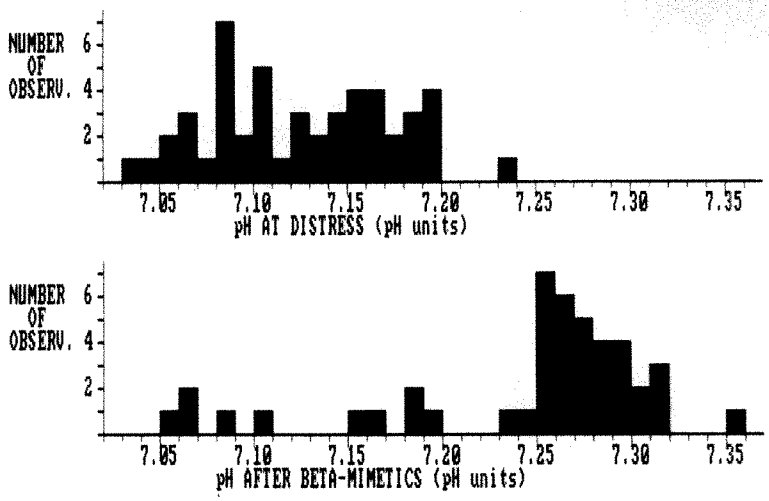

Fig. 2. *Top*: During fetal distress all fetuses but one (see text) had a pH lower than 7.20. After tocolysis *(bottom)* in 37 fetuses pH was >7.18 and in 34 it was >7.23. The modal pH after tocolysis was 7.25. All sampled cases are included. (See also Table I.)

Table II. Analysis of variance for repeated measures including only the fetuses with successful sampling before, during, and after tocolysis (F value = 87.29, $p < 0.0005$)

	pH		
	Mean	*SD*	*n*
Before distress	7.266	0.046	37
During distress	7.121	0.045	37
After tocolysis	7.242	0.071	37

and at the time of distress all fetuses had a capillary blood pH <7.20, except for one fetus with a diagnosis of fetal distress because the pH decreased from 7.34 to 7.23 in 65 minutes (see Fig. 2, *top*). After the administration of β_2-sympathomimetics, the average scalp pH rose from 7.121 to 7.239 (Table I); in 37 of the 44 fetuses sampled before delivery (84.1%) the pH was >7.18 and in 34 of them (77.3%) the pH was >7.23 (Fig. 2, *bottom*).

The statistical analysis of the pH values obtained in the 37 fetuses who were sampled before, during, and after distress (after β_2-sympathomimetics) showed overall significant differences for the three conditions (Table II). The difference between the mean values obtained before distress and after β_2-sympathomimetics was not significant, whereas the differences between the values recorded before and during distress and those during distress and after β_2-sympathomimetics were significant (Table III).

The pH values of the umbilical vein blood samples (mean = 7.256; SD = 0.072) were similar to those measured in the scalp after the administration of β_2-sympathomimetics (Table I). In 41 of them (87.2%) the pH was >7.19 and in 40 (81.1%) it was >7.24.

After administration of β_2-sympathomimetics, a marked improvement in the fetal heart rate accompanying the fetal pH increase was noticed in 34 of the 41 patients having reliable fetal heart rate tracings. In one patient (No. 21) the fetal pH remained unchanged at 7.08, although ritodrine succeeded in suppressing the uterine contractions and the fetal heart rate rose from 85 to 125 bpm.* The remaining six fetuses, who showed no definite changes either in the heart rate or in the scalp pH after the administration of β_2-sympathomimetics, were promptly delivered by cesarean section (five patients) or forceps (one patient, No. 35). The clinical complications identified in these fetuses are listed in Table IV.

The fetal acidosis (Tables I and III) developed quite rapidly (average 45.1 minutes) and after tocolysis the pH recovered even faster (average 37.1 minutes, see Table V). As mentioned above, the pH changes recorded from normal to distress and from distress to after tocolysis (Table III) were very similar.

Most patients (40) were delivered by cesarean section, under general or epidural anesthesia.† Nine patients were close to full dilatation when fetal distress developed; eight of these fetuses recovered during tocolysis and subsequently uterine contractions were allowed to reestablish. Five of them were delivered by forceps application and three had a normal spontaneous vaginal

*This 41-week-old fetus was delivered by a cesarean section 25 minutes after being diagnosed with fetal distress, with Apgar scores of 3 and 4 (at the first and fifth minute, respectively) and a body weight of 2250 gm. We have no satisfactory explanation for this unusual behavior.

†Some cesarean sections were performed with the patients under epidural anesthesia because they were already under that anesthesia during labor.

Table III. Differences in mean pH values

Time	*Difference*	*SD*	t	*p*	*n*
Before distress–during distress	0.145	0.046	19.79	<0.0005	39
Before distress–after tocolysis	0.024	0.082	1.76	0.087	37
During distress–after tocolysis	−0.118	0.085	−9.26	0.0005	44

Difference in values before distress and after tocolysis was not significant (paired Student's *t* test, $p = 0.087$). Differences in values before distress and during distress and during distress and after tocolysis were significant ($p < 0.005$).

Table IV. Clinical complications identified in fetuses who showed no definite improvement in heart rate and pH after β_2-sympathomimetics

Fetal pH		*Apgar score*		
At distress	*After β_2-sympathomimetics*	*1 min*	*5 min*	*Clinical complications*
7.06	7.12	4	6	Intrauterine growth retardation, short cord
7.10	7.10	5	5	Class B diabetes
7.15	7.12	5	6	Short cord
7.05	7.07	3	6	Abruptio placentae
7.06	7.05	3	5	Tight true knot, short cord
7.18	7.16	2	3	Multiple congenital malformations

Table V. Time elapsed (in minutes) between fetal samples obtained before and during fetal distress and during fetal distress to after tocolysis

Time	*Mean*	*SD*	*n*
Before distress–during distress	45.1	27.97	39
During distress–after tocolysis	37.1	15.3	47

Table VI. List of clinical complications probably responsible for fetal distress

Complication	*No. of patients*
Cord complication	21
Preeclampsia	9
Unknown	8
Placental lesions	6
Intrauterine growth retardation	4
Oligohydramnios	4
Diabetes	3
Postmaturity	2
Congenital malformation	2
Hypercontractility	2

delivery. All of them had Apgar scores of ≥7 at the first minute. The remaining patient (No. 35) showed no fetal improvement with tocolysis and was delivered as an emergency by forceps (Apgar scores of 3 and 5 at the first and fifth minutes).

No fetal or early neonatal losses occurred in this series and the clinical progress of these neonates was unremarkable, except for one infant who died on the tenth day of extrauterine life as a consequence of multiple congenital malformations. A low one-minute Apgar score (≤6) was found in 13 of the 49 newborn infants (26.5%), although four of these had a scalp pH >7.25 before delivery and in the umbilical vein blood. At 5 minutes of extrauterine life, 43 neonates had an Apgar score of ≥7.

The clinical complications probably responsible for the fetal distress are listed in Table VI and those identified in the six patients who showed no improvement with β_2-sympathomimetics are presented in Table IV.

Detailed maternal data on cardiovascular and neurological side effects are available only for the patients who received ritodrine or orciprenaline. At the therapeutic dose level, these patients had a significantly increased ($p < 0.005$) average heart rate, from 74.3 to 98.4 bpm. The average systolic and diastolic pressures remained almost unchanged (128 to 132 and 72.1 to 70.0 mm Hg, respectively). Well-tolerated mild tremors and nervousness were reported in 11 patients, 10 of them with orciprenaline and one with ritodrine. The average fetal heart rate increased 21.0 bpm ($p < 0.01$). Spontaneous or oxytocin-induced postpartum uterine contractility was normal in all cases.

The estimated maternal blood loss was under 500 ml in vaginal deliveries and under 1000 ml in cesarean sections. No neonatal complications were identified that could be related to the use of β_2-sympathomimetics.

Comment

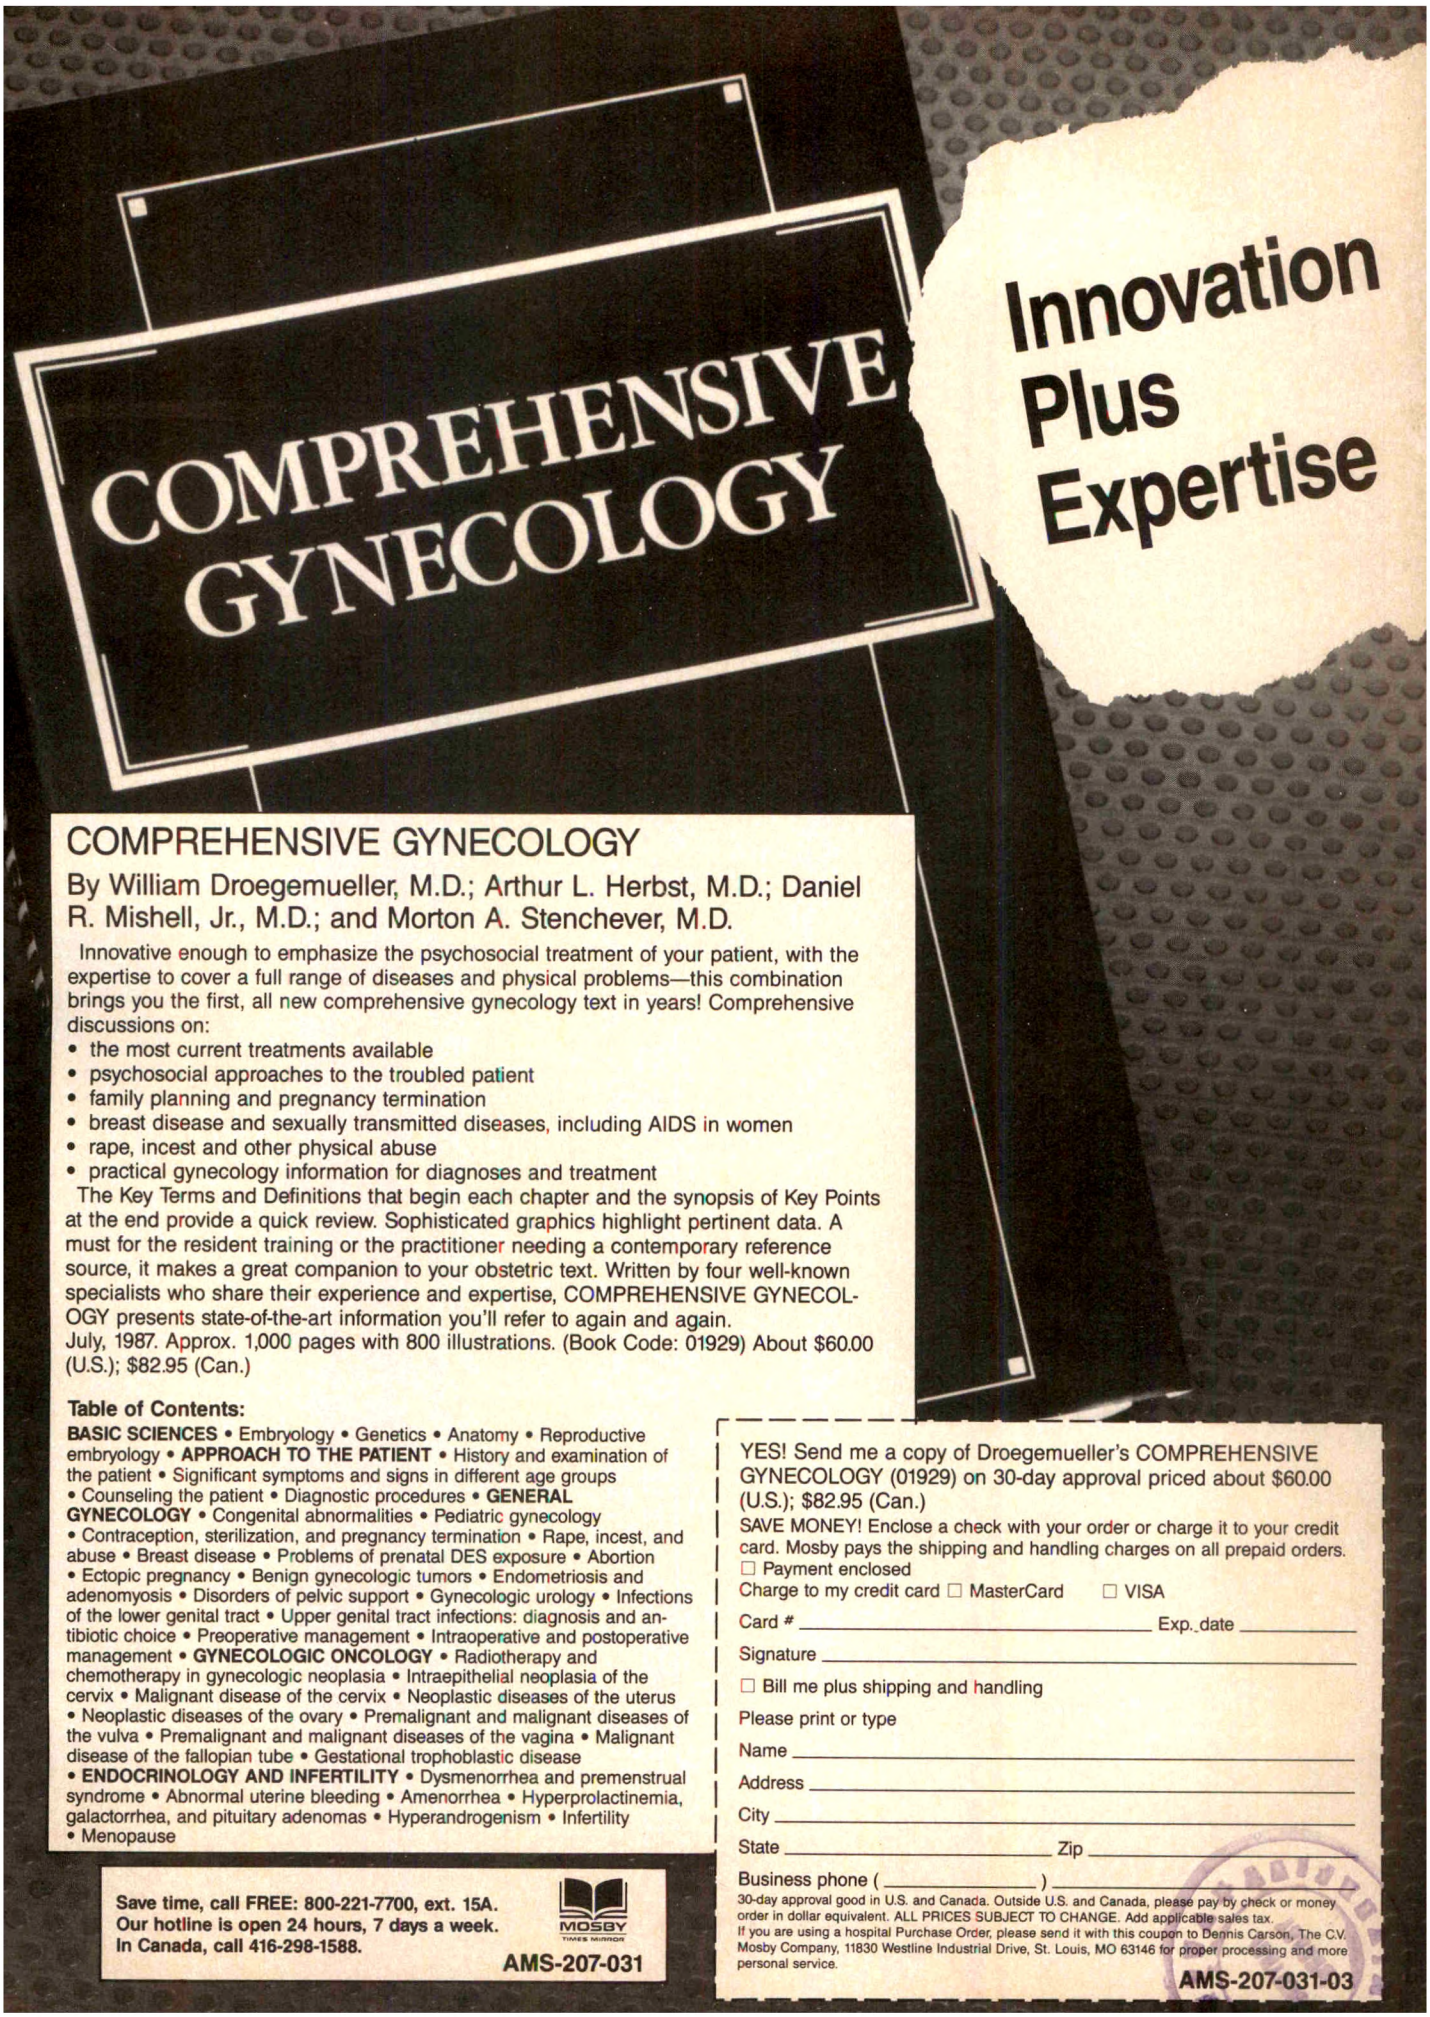
The outcome of this series, in terms of umbilical blood pH and perinatal mortality and morbidity, is definitely closer to that of a normal population than to that of a group of seriously distressed fetuses. This is very intriguing when the marked degree of acidosis developed by most of these fetuses is considered (Figs. 1 and 2, Tables I, II, and III) and their rapid deterioration (Table V). Assuming a linear relationship

between the pH change from normal to distress and the time elapsed,[1, 16] the resulting average value (0.0037 pH units per minute, SD = 0.002) would classify these fetuses as having acute or even superacute fetal distress according to Saling's classification.[1, 16]

After tocolysis, most of these fetuses recovered almost as rapidly as they deteriorated (Table V), which suggests that the uterine contractions were the major distressing factor since, as soon as they disappeared, the placental function sufficed to rapidly correct fetal acidosis. We may conclude that the fetal improvement observed after tocolysis was mainly determined by the inhibition of uterine contractions, although some direct influence of these drugs on the fetomaternal homeostasis and cardiac output[5, 7, 10, 12-15] cannot be totally excluded.

In six fetuses, tocolysis failed to restore the fetal homeostasis. The kind of complication identified as the probable cause of distress in these fetuses (Table II) may explain why in utero inhibition was unable to improve fetal condition. When fetal acidosis results from a tight true knot or a short umbilical cord, an extensive abruptio placentae, or a fetal cardiovascular malformation, it will not be corrected only by suppressing uterine contractions. The main cause for fetal compromise in these cases is a very serious impairment of placental or fetal function and the ischemic effect of contractions on the maternal blood flow through the intervillous space plays a very secondary role.

With only one exception, the fetal heart rate closely reflected the improvement of fetal acidosis. A practical consequence of this finding is that when β_2-sympathomimetics are used to treat fetal distress, the evolution of fetal pH can be reasonably predicted by a careful evaluation of the fetal heart rate tracing. When the fetal heart rate bradycardia, late decelerations, or serious variable pattern fades out, a progressive recovery of fetal acidosis usually follows. These fetuses may remain "in utero," enabling the placenta to balance the altered fetal homeostasis before birth and lead to the delivery of a vigorous neonate, with an already corrected acidosis, a good cardiovascular function, and a favorable prognosis. When the fetal heart rate remains ominous, no improvement in fetal homeostasis is to be expected; these fetuses should be delivered as soon as possible. Ideally, the obstetric team should be ready to perform an emergency cesarean section when no improvement in the fetal heart rate is detected after tocolysis.



Finally, it should be noted that cesarean section was avoided in a few cases (nine vaginal deliveries, 18.36%) primarily because the fetal distress occurred when the cervix was close to full dilatation and the lapse without contractions allowed the recovery from fetal acidosis.

Considering the benefits obtained from the use of tocolysis, that is, the lack of maternal, fetal, and neonatal mortality, the reduced perinatal morbidity, and the mild side effects observed by us and other authors, we can conclude that there is enough evidence to support the use of β_2-sympathomimetics in treating acute intrapartum fetal distress if the proper technique and indications are followed.

We want to thank Dr. Marija Norusis, Associate Professor, Preventive Medicine, Rush-Presbyterian–Saint Luke's University, Chicago, Illinois, for kindly supervising the statistical analysis of the data.

COMPREHENSIVE GYNECOLOGY

By William Droegemueller, M.D.; Arthur L. Herbst, M.D.; Daniel R. Mishell, Jr., M.D.; and Morton A. Stenchever, M.D.

Innovative enough to emphasize the psychosocial treatment of your patient, with the expertise to cover a full range of diseases and physical problems—this combination brings you the first, all new comprehensive gynecology text in years! Comprehensive discussions on:

- the most current treatments available
- psychosocial approaches to the troubled patient
- family planning and pregnancy termination
- breast disease and sexually transmitted diseases, including AIDS in women
- rape, incest and other physical abuse
- practical gynecology information for diagnoses and treatment

The Key Terms and Definitions that begin each chapter and the synopsis of Key Points at the end provide a quick review. Sophisticated graphics highlight pertinent data. A must for the resident training or the practitioner needing a contemporary reference source, it makes a great companion to your obstetric text. Written by four well-known specialists who share their experience and expertise, COMPREHENSIVE GYNECOLOGY presents state-of-the-art information you'll refer to again and again.
July, 1987. Approx. 1,000 pages with 800 illustrations. (Book Code: 01929) About $60.00 (U.S.); $82.95 (Can.)

Table of Contents:

BASIC SCIENCES • Embryology • Genetics • Anatomy • Reproductive embryology • **APPROACH TO THE PATIENT** • History and examination of the patient • Significant symptoms and signs in different age groups • Counseling the patient • Diagnostic procedures • **GENERAL GYNECOLOGY** • Congenital abnormalities • Pediatric gynecology • Contraception, sterilization, and pregnancy termination • Rape, incest, and abuse • Breast disease • Problems of prenatal DES exposure • Abortion • Ectopic pregnancy • Benign gynecologic tumors • Endometriosis and adenomyosis • Disorders of pelvic support • Gynecologic urology • Infections of the lower genital tract • Upper genital tract infections: diagnosis and antibiotic choice • Preoperative management • Intraoperative and postoperative management • **GYNECOLOGIC ONCOLOGY** • Radiotherapy and chemotherapy in gynecologic neoplasia • Intraepithelial neoplasia of the cervix • Malignant disease of the cervix • Neoplastic diseases of the uterus • Neoplastic diseases of the ovary • Premalignant and malignant diseases of the vulva • Premalignant and malignant diseases of the vagina • Malignant disease of the fallopian tube • Gestational trophoblastic disease • **ENDOCRINOLOGY AND INFERTILITY** • Dysmenorrhea and premenstrual syndrome • Abnormal uterine bleeding • Amenorrhea • Hyperprolactinemia, galactorrhea, and pituitary adenomas • Hyperandrogenism • Infertility • Menopause

What's the difference between
OVCON®
(norethindrone [0.4 mg] and ethinyl estradiol [0.035 mg]) tablets
35
...and Tri-Norinyl®
Ortho-Novum™ 7/7/7,&
Ortho-Novum™ 1/35?

they contain 78% to 150% more norethindrone per cycle!

the OC with the lowest norethindrone dose

OVCON®-35

(norethindrone [0.4 mg] and ethinyl estradiol [0.035 mg]) tablets

Mead Johnson

OVCON®-50

(norethindrone [1 mg] and ethinyl estradiol [0.05 mg]) tablets

OVCON®-35

(norethindrone [0.4 mg] and ethinyl estradiol [0.035 mg]) tablets

Indications and Usage: Ovcon is indicated for the prevention of pregnancy. Some combination products containing 35 mcg. or less of ethinyl estradiol report slightly higher pregnancy rates than are reported for the higher dose combination products.

Dose-related Risk of Thromboembolism from Oral Contraceptives: Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing 50 mcg. or less of estrogen.

Contraindications: Oral contraceptives should not be used in women with any of the following conditions: 1) Thrombophlebitis or thromboembolic disorders. 2) A past history of deep vein thrombophlebitis or thromboembolic disorders. 3) Cerebral vascular or coronary artery disease. 4) Known or suspected carcinoma of the breast. 5) Known or suspected estrogen dependent neoplasia. 6) Undiagnosed abnormal genital bleeding. 7) Known or suspected pregnancy. 8) Benign or malignant liver tumor which developed during the use of oral contraceptives or other estrogen-containing products.

Warnings:

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. Women who use oral contraceptives should be strongly advised not to smoke. Use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1) *Thromboembolic Disorders and Other Vascular Problems.* An increased risk of thromboembolic and thrombotic disease associated with use of oral contraceptives is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. In a study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater. An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported. Studies conducted in the United Kingdom found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction compared to nonusers who do not smoke. Oral contraceptive users who smoke have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. The amount of smoking is a very important factor. British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives; preparations containing 100 mcg. or more of estrogen were associated with a higher risk of thromboembolism than those containing 50–80 mcg. of estrogen. The relative risk of thromboembolic disease associated with progestin-only oral contraceptives has not been determined. Cases of thromboembolic disease have been reported in women using progestin-only products, and they should not be presumed to be risk-free. The overall excess mortality rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15–34, 5/100,000; ages 35–44, 33/100,000; ages 45–49, 140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. The highest risk was found in heavy cigarette smokers (15 or more cigarettes per day) who used oral contraceptives and were aged 40 or older. Women who smoke should be advised not to use oral contraceptives. The use of oral contraceptives in women over age 40 with other risk factors is not recommended. The mortality associated with all of the methods of birth control is low compared to the risk of childbirth, with the exception of oral contraceptive users who smoke and are over age 40. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and for myocardial infarction is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia, and especially by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. If feasible, oral contraceptives should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2) *Ocular Lesions.* There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue the medication if there is unexplained sudden or gradual, partial or complete loss of vision; sudden onset of proptosis or diplopia; papilledema; or retinal vascular lesions, and institute appropriate diagnostic and therapeutic measures. 3) *Carcinoma.* Long term administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. In humans, one study investigated the first 21 cases of endometrial adenocarcinoma in women on oral contraceptives reported to a registry. Of those women without predisposing risk factors for this disease, nearly all occurred in women who had used a sequential oral contraceptive. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestin-only oral contraceptives. No increase in breast cancer in women taking oral contraceptives has been reported although one study reported an increased risk of breast cancer in subgroups of women treated using oral contraceptives with documented benign breast disease. There is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives. 4) *Hepatic Adenoma.* Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study reported a higher risk associated with oral contraceptive formulations with high hormonal potency. Although benign and rare, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short term as well as long term users of oral contraceptives. Two studies relate the risk with duration of contraceptive use, the risk being much greater after 4 or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass, or shock. A few cases of hepatocellular carcinoma have been reported in women taking oral contraceptives. The relationship of these drugs to this type of malignancy is not known at this time. 5) *Use in Pregnancy; Birth Defects in Offspring and Malignancy in Female Offspring.* Fetal abnormalities have been reported to occur in the offspring of women who have taken progestogens and/or estrogens during pregnancy. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. A high percentage of such exposed women (30% to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Similar data are not available with the use of other estrogens but it cannot be presumed that they would not induce similar changes. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000 live births. In the past, female there is no evidence from well-controlled studies that progestins are effective for these uses. Increases in chromosomal aberrations have been reported in women who become pregnant soon after ceasing oral contraceptive therapy. Embryos with these anomalies are virtually always spontaneously aborted. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed the patient should be apprised of the potential risks to the fetus and the advisability of pregnancy continuation should be discussed in light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months. Administration of progestin-only or progestin-estrogen combinations to induce withdrawal bleeding should not be used as a test for pregnancy. 6) *Gall Bladder Disease.* Studies have reported an increased risk of surgically confirmed gallbladder disease appearing after one year of oral contraceptive use and doubling of the risk after 4 or 5 years of use. 7) *Carbohydrate and Lipid Metabolic Effects.* A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. Increased serum levels of triglycerides and total phospholipids have been observed in oral contraceptive users. The clinical significance of this observation is unknown at this time. 8) *Elevated Blood Pressure.* An increase in blood pressure has been reported in women receiving oral contraceptives. The prevalence of hypertension in oral contraceptive users may be no higher than nonusers in the first year of oral contraceptive use but increases with longer exposure and in the fifth year of use is two and one-half to three times the reported prevalence in the first year. Women who previously had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. 9) *Headaches.* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of oral contraceptives and investigation of the cause. 10) *Bleeding Irregularities.* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. 11) *Ectopic Pregnancy.* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. However, in oral contraceptive failures, the ratio of ectopic to intrauterine pregnancies is higher than in women not using oral contraceptives since the drugs are more effective in preventing intrauterine rather than ectopic pregnancy. The higher ectopic-intrauterine ratio has been reported with both combination products and progestin-only oral contraceptives. 12) *Breast Feeding.* A small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The long-range effect to the nursing infant cannot be determined at this time.

Precautions: 1) A complete medical and family history should be taken prior to the initiation of oral contraceptives. Examination should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than 1 year without another physical examination being performed. 2) Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3) Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 4) Because oral contraceptives may cause some degree of fluid retention, conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, cardiac or renal insufficiency or asthma require careful observation. 5) Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6) Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7) Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8) Serum folate levels may be depressed by oral contraceptive therapy. This may complicate subsequent pregnancy with regard to folate deficiency. 9) The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. 10) Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T_4 by column, or T_4 by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. 11) The active yellow tablets and the inert green tablets in Ovcon-50 (21 and 28 day regimens) and the inert green tablets in the 28 day regimen of Ovcon-35 contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

Information for the Patient: Detailed Patient Labeling has been prepared for use by the patient and has been made available for distribution by the pharmacist.

Drug Interactions: Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Adverse Reactions: An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **Warnings**): Thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis; benign hepatomas, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10% or less of patients during the first cycle (other reactions, as a general rule, are seen much less frequently or only occasionally); gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes (tenderness, enlargement, and secretion); change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; changes in corneal curvature (steepening), intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria.

Acute Overdosage: Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

MJL 6-4184

FACULTY OF MEDECINE UNIVERSITY OF MONTREAL

The Department of obstetrics-gynecology invites application for a faculty position in perinatalogy at the Pediatric Research Center of Ste-Justine Hospital to be filled from June 1st, 1987. Candidates should hold a M.D., be certified specialist in obstetrics-gynecology and have a two-year minimum research training. A good working knowledge of the French language is required. Curriculum viate with description of research interests should be submitted by April 15, 1987 to:

Dr. Yves Lefebvre
Chairman
Dept. of obstetrics-gynecology
Faculty of Medicine
University of Montreal
P.O. Box 6128, Station A
Montreal (QUEBEC) H3C 3J7

In accordance with Canadian immigration requirements, priority will be given to Canadian citizens and permanent residents.

SEATTLE GROUP PRACTICE

Fast growing women's OB/GYN Group practice

Associated with a major Seattle medical center. First year income guarantee. Malpractice and benefits provided. Practice structured to support personal as well as professional goals. High-quality medical community. New delivery facilities, strong Family Practice Residency and Department.

For information:

The Friedrich Group, Inc.
9284 Ferncliff Northeast
Bainbridge Island, WA 98110
(206) 547-7850
(206) 842-5248

FACULTY POSITION

The Knoxville Unit of The University of Tennessee College of Medicine is currently accepting applications for general specialists in the Department of Obstetrics and Gynecology at The University of Tennessee Medical Center at Knoxville.

This position requires board certification or eligibility in Obstetrics and Gynecology. Responsibilities include: resident and medical student education; participation in Regionalization Program; and clinical or basic research.

Specialized areas of interest such as: adolescent GYN; GYN urology; benign GYN surgery; and/or reproductive immunology are encouraged.

Academic rank is commensurate with qualifications and experience.

Interested persons should send curriculum vitae to:

Chairman, Department of Obstetrics and Gynecology
University of Tennessee Medical Center
1924 Alcoa Highway
Knoxville, TN 37920
(615) 544-9306

UT

An Affirmative Action/Title IX/Section 504 Employer

OBSTETRICIAN GYNECOLOGIST

Position available with The Permanente Medical Group, Inc., San Jose, California. Sixteen member OB/GYN Department seeking Board Certified/Eligible physicians for immediate openings. Excellent professional environment, competitive salary, outstanding benefits. Located in the San Francisco Bay Area, with superb educational, cultural and recreational activities.

Please see brief summary of prescribing information on last page of this advertisement.

Cefizox®

brand of

sterile ceftizoxime sodium and ceftizoxime sodium injection

Before prescribing, see complete prescribing information in SK&F literature or *PDR*. The following is a brief summary.

INDICATIONS

'Cefizox' is indicated in the treatment of infections due to susceptible strains of the microorganisms listed below:

LOWER RESPIRATORY TRACT INFECTIONS caused by *Streptococcus* sp. including *S. pneumoniae* (formerly *D. pneumoniae*), but excluding enterococci; *Klebsiella* sp.; *Proteus mirabilis; Escherichia coli; Haemophilus influenzae* including ampicillin-resistant strains; *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Serratia* sp.; *Enterobacter* sp.; and *Bacteroides* sp.

URINARY TRACT INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Escherichia coli; Pseudomonas* sp. including *Ps. aeruginosa; Proteus mirabilis; P. vulgaris; Providencia rettgeri* (formerly *Proteus rettgeri*) and *Morganella morganii* (formerly *Proteus morganii*); *Klebsiella* sp.; *Serratia* sp. including *S. marcescens; Enterobacter* sp.

GONORRHEA. Uncomplicated cervical and urethral gonorrhea caused by *Neisseria gonorrhoeae.*

INTRA-ABDOMINAL INFECTIONS caused by *Escherichia coli; Staphylococcus epidermidis; Streptococcus* sp. (excluding enterococci); *Enterobacter* sp.; *Klebsiella* sp.; *Bacteroides* sp. including *B. fragilis;* and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

SEPTICEMIA caused by *Streptococcus* sp. including *S. pneumoniae* (formerly *D. pneumoniae*), but excluding enterococci; *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Escherichia coli; Bacteroides* sp. including *B. fragilis; Klebsiella* sp.; and *Serratia* sp.

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Staphylococcus epidermidis; Escherichia coli; Klebsiella* sp.; *Streptococcus* sp. including *Streptococcus pyogenes* (group A beta-hemolytic), but excluding enterococci; *Proteus mirabilis; Serratia* sp.; *Enterobacter* sp.; *Bacteroides* sp. including *B. fragilis;* and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

BONE AND JOINT INFECTIONS caused by *Staphylococcus aureus* (penicillinase and nonpenicillinase producing); *Streptococcus* sp. (excluding enterococci); *Proteus mirabilis; Bacteroides* sp.; and anaerobic cocci, including *Peptococcus* sp. and *Peptostreptococcus* sp.

MENINGITIS caused by *Haemophilus influenzae*. 'Cefizox' has also been used successfully in the treatment of a limited number of pediatric and adult cases of meningitis caused by *Streptococcus pneumoniae.*

'Cefizox' has been effective in the treatment of seriously ill, compromised patients, including those who were debilitated, immunosuppressed or neutropenic.

Many infections caused by aerobic gram-negative organisms and by mixtures of organisms resistant to other cephalosporins, aminoglycosides, or penicillins respond to treatment with 'Cefizox'.

Because of the serious nature of some urinary tract infections due to *Ps. aeruginosa* and because many strains of *Pseudomonas* species are only moderately susceptible to 'Cefizox', higher dosage is recommended. Other therapy should be instituted if the response is not prompt.

Susceptibility studies on specimens obtained prior to therapy should be used to determine the response of causative organisms to 'Cefizox'. Therapy with 'Cefizox' may be initiated pending results of the studies; however, treatment should be adjusted according to study findings. In serious infections 'Cefizox' has been used concomitantly with aminoglycosides (see Precautions). Before using 'Cefizox' concomitantly with other antibiotics, the prescribing information for those agents should be reviewed for contraindications, warnings, precautions and adverse reactions. Renal function should be carefully monitored.

CONTRAINDICATIONS

'Cefizox' is contraindicated in persons who have shown hypersensitivity to cephalosporin antibiotics.

WARNINGS

BEFORE THERAPY WITH 'CEFIZOX' IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. THIS PRODUCT SHOULD BE GIVEN CAUTIOUSLY TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis **has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who developed diarrhea in association with antibiotic use.** Treatment with broad-spectrum antibiotics alters normal flora of the colon and may permit overgrowth of *Clostridia*. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin *in vitro*. Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C. difficile*. Other causes of colitis should also be considered.

PRECAUTIONS

General: As with all broad-spectrum antibiotics, 'Cefizox' should be prescribed with caution in individuals with a history of gastrointestinal disease, particularly colitis.

Although 'Cefizox' has not been shown to produce an alteration in renal function, renal status should be evaluated, especially in seriously ill patients receiving maximum dose therapy. As with any antibiotic, prolonged use may result in overgrowth of nonsusceptible organisms. Careful observation is essential; appropriate measures should be taken if superinfection occurs.

Drug Interactions: Although the occurrence has not been reported with 'Cefizox,' nephrotoxicity has been reported following concomitant administration of other cephalosporins and aminoglycosides.

Pregnancy: (Category B.) Reproduction studies have been performed in rats and rabbits and have revealed no evidence of impaired fertility or harm to the fetus due to 'Cefizox'. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Labor and Delivery: Safety of 'Cefizox' use during labor and delivery has not been established.

Nursing Mothers: 'Cefizox' is excreted in human milk in low concentrations. Caution should be exercised when 'Cefizox' is administered to a nursing woman.

Infants and Children: Safety and efficacy in infants from birth to six months of age have not been established. In children six months of age and older, treatment with 'Cefizox' has been associated with transient elevated levels of eosinophils, SGOT, SGPT and CPK (creatine phosphokinase). The CPK elevation may be related to I.M. administration.

ADVERSE REACTIONS

Ceftizoxime is generally well tolerated; the *most* frequent adverse reactions (*greater than* 1%, but less than 5%) are: *Hypersensitivity*—Rash, pruritus, fever. *Hepatic*—Transient elevation in SGOT, SGPT and alkaline phosphatase. *Hematologic*—Transient eosinophilia, thrombocytosis. Some individuals have developed a positive Coombs test. *Local*—Injection site—Burning, cellulitis, phlebitis with I.V. administration, pain, induration, tenderness, paresthesia.

Less frequent adverse reactions (*less than* 1%) are: *Hypersensitivity*—Numbness has been reported rarely. *Hepatic*—Elevation of bilirubin has been reported rarely. *Renal*—Transient elevations of BUN and creatinine have been occasionally observed with ceftizoxime. *Hematologic*—Anemia, leukopenia, neutropenia and thrombocytopenia have been reported rarely. *Genitourinary*—Vaginitis has rarely occurred. *Gastrointestinal*—Diarrhea; nausea and vomiting have been reported occasionally. Symptoms of pseudomembranous colitis can appear during or after antibiotic treatment. (See Warnings.)

HOW SUPPLIED

Cefizox (sterile ceftizoxime sodium, FSK) is supplied in vials equivalent to 1 gram or 2 grams of ceftizoxime; in "Piggyback" Vials for I.V. admixture equivalent to 1 gram or 2 grams of ceftizoxime.

Cefizox (ceftizoxime sodium injection, FSK) as a frozen, sterile, nonpyrogenic solution in plastic containers—supplied in 50 ml. single-dose containers equivalent to 1 gram or 2 grams of ceftizoxime, in 5% Dextrose (D5W). Do not store above -20°C.

'Cefizox' supplied as a frozen, sterile, nonpyrogenic solution in plastic containers is manufactured for Fujisawa SmithKline Corporation by Travenol Laboratories, Inc., Deerfield, IL 60015.

Upper airway obstruction as a cause of pulmonary edema during late pregnancy

Urs Lagler, M.D., and Erich Russi, M.D.
Zurich, Switzerland

We describe a 35-year-old woman who developed pulmonary edema at 38 weeks of pregnancy as a result of upper airway obstruction caused by a progressively enlarging euthyroid goiter. (AM J OBSTET GYNECOL 1987;156:643-4.)

Key words: Pulmonary edema, pregnancy, upper airways obstruction, goiter

Pulmonary edema in pregnant women without preexisting heart disease may be caused by the use of β-mimetic agents for preterm labor, by severe hypertension of preeclampsia, by amniotic fluid embolism, or by septic events during delivery.

Case report

A 35-year-old Albanian woman at 38 weeks of gestation was admitted in a semicomatose, cyanotic state with extreme shortness of breath with an inspiratory stridor.

A mild euthyroid goiter had been present for 2 years. During her pregnancy, which otherwise was normal, she noticed a progressive enlargement of her thyroid gland together with dysphagia and posture-dependent dyspnea. She was finally unable to sleep unless in a sitting position. There was no history of preeclampsia, high blood pressure, or congestive heart failure.

On admission the patient was immediately intubated without difficulty with a 7.0 mm diameter endotracheal tube, and copious amounts of white foamy secretions were suctioned from the airways. Chest radiographic studies confirmed the clinical diagnosis of severe pulmonary edema. Blood pressure was 80/60 mm Hg; analysis of arterial blood gas, drawn immediately after intubation and during ventilation with an $F_{I_{O_2}}$ of 1.0, revealed a P_{O_2} of 54 mm Hg and a pH of 7.30. The pulmonary edema cleared within hours. Since the child's heart rate pattern deteriorated, a cesarean section was performed and a viable boy was delivered. The postoperative course was without complications, and the patient remained stable and well oxygenated on the ventilator. Blood pressure was 120/80 mm Hg and the pulse rate 80 per minute and regular. A cardiac ultrasound scan revealed normal chamber diameters with good contractility and no sign of mitral stenosis.

After 24 hours the patient was extubated; 45 minutes later she became severely cyanotic, tachypneic, and short of breath and developed a massive inspiratory stridor. Again an endotracheal tube was inserted without difficulties. Flexible fiberoptic bronchoscopy revealed mild laryngeal edema and a normal tracheal diameter distal to the tip of the endotracheal tube. By retracting the tube we found a 70% slit-form tracheal stenosis 7 cm above the carina caused by extrinsic compression. No malignant cells were found by fine needle aspiration of the goiter. The trachea was decompressed by subtotal strumectomy: no tracheomalacia was present. The histologic examination revealed a macrofollicular goiter. The postoperative course was uneventful.

Comment

We believe that pulmonary edema in this patient was caused by severe upper airway obstruction. The absence of a history of toxemia, arterial hypertension, left ventricular dysfunction, or valvular heart disease makes other causes of pulmonary edema in late pregnancy unlikely. Furthermore, the patient was not receiving β-mimetics and there was no evidence of amniotic fluid embolism. A strikingly similar case was reported by Stradling and Bolton.[1] Pulmonary edema caused by upper airway obstruction has been reported secondary to tumor, strangulation, and interrupted hanging and in children with croup and epiglottitis; it can be induced experimentally in dogs by increasing the inspiratory resistance.[2]

A normal pregnancy in a healthy woman does not result in pulmonary edema but may create a fragile pulmonary water balance. Blood volume is expanded: plasma volume increases by 50% in normal primagravid women and red cell mass by 18% to 30%. Furthermore, the colloid-oncotic pressure of plasma falls by about 7 cm of water. Thus it can be speculated that the fluid shift from the pulmonary capillaries to the

alveolar space caused by complex intrathoracic pressure changes resulting from repeated Mueller maneuvers may be facilitated by the expanded intravascular volume during late pregnancy.

Symphysis-fundus height, maternal height, labor pattern, and mode of delivery

Alan B. Hughes, M.D., D. Adam Jenkins, M.B., B.S., B.Sc., Robert G. Newcombe, Ph.D., and James F. Pearson, M.D.

Cardiff, Wales

Fetal growth was monitored with use of symphysis-fundus charts in 920 consecutive term singleton pregnancies with cephalic presentation. There were 402 primigravid and 518 multigravid patients. The symphysis-fundus charts were divided into four zones and the patients allocated into groups according to the zone of the last symphysis-fundus height measurement before the onset of labor. A highly significant increase was noted in the incidence of abnormal labor and operative delivery in group A primigravid women (symphysis-fundus height above the ninetieth centile), which was even more pronounced when the effect of epidural analgesia was excluded. Conversely, there was a significant progressive increase in the proportion of operative deliveries for fetal distress from group A through group D (symphysis-fundus height below the tenth centile). Similar trends were significant but less pronounced among multigravid women. The relationship between maternal height, symphysis-fundus height, and operative delivery for dystocia in primigravid women was examined. High operative delivery rates were present in group A primigravid patients regardless of maternal height. In groups B and C, however, increased maternal height was associated with lower operative delivery rates. (Am J Obstet Gynecol 1987;156:644-8.)

Key words: Symphysis-fundus height, maternal height, labor pattern, mode of delivery

Currently there is a resurgence of interest in low-cost clinical methods of measuring fetal growth. One such method that has achieved acceptance is the symphysis-fundus height chart.[1-4] It seemed to us that these charts could be further used to provide information of prognostic value during labor. For instance, one might expect the large infant to be at greater hazard from dystocia than from asphyxia, and conversely, the small infant to be at greater risk from asphyxia than from dystocia. Since fetal growth is reflected by symphysis-fundus height, reference to the pattern of symphysis-fundus growth might direct the attention of the obstetrician toward certain problems more likely to be encountered in labor. The present investigation attempts to examine this postulate and quantify this relationship.

Patients and methods

Nine hundred twenty consecutive term singleton pregnancies with cephalic presentation were analyzed according to labor pattern and mode of delivery. There were 402 primigravid and 518 multigravid patients.

Fetal growth was monitored with use of the symphysis-fundus charts of Calvert et al.[4] (Fig. 1). Measurements were made by lightly marking the position of the uterine fundus while the patient was supine. The end of a nonelastic tape measure was held against the fixed point (symphysis) and the distance to the mark on the patient's skin recorded. Whole digit preference was decreased by use of a tape marked in inches on one side and centimeters on the other. The measurement was initially made in inches, then the tape turned

over, and the corresponding metric value recorded to the nearest half centimeter. This method has a low intraobserver coefficient of variation (4.6%) and a low interobserver coefficient of variation (6.4%). The symphysis-fundus chart was divided into four zones (Fig. 1): zone A (symphysis-fundus height above the ninetieth centile line), zone B (between the fiftieth and ninetieth centile lines), zone C (between the tenth and fiftieth centile lines), and zone D (below the tenth centile line). Patients were grouped according to the zone of the last symphysis-fundus height measurement before the onset of labor.

Gestational age was confirmed by ultrasound in early pregnancy in every case. During labor the use of continuous electronic fetal heart rate monitoring and of composite partograms as described by Studd et al.[5] was routine. Continuous lumbar epidural analgesia was provided when clinically indicated or requested by the patient and used in 27% of the primigravid and 6% of the multigravid patients. Oxytocin augmentation of labor was provided for 23% of the primigravid and 4% of the multigravid patients.

The labor pattern was considered to be normal if the rate of cervical dilatation during the active phase was at least 1.2 cm/hr in primigravid women and 1.5 cm/hr in multigravid ones.[6]

We have used the term "active-phase dystocia" to include protracted active-phase dilatation (primary dysfunctional labor), secondary arrest, and prolonged deceleration phase. The duration of the latent phase of labor was excluded from analysis. "Second-stage delay" was interpreted as having occurred when operative intervention was required for "failure to progress." This was usually compatible with Friedman's limits of 1.1 hours for multigravid patients. However, in the United Kingdom, the second stage of labor has been regarded as a time of particular risk for progressive fetal acidosis.[7, 8] Consequently for primigravid patients a time limit of 1½ hours was usually recommended before intervention with assisted delivery.

The primigravid population was subdivided according to height. "Short" stature was taken as a height of ≤156 cm, as defined by Baird,[9] and "tall" stature was defined as a height of >168 cm, so that the proportion of tall women (19%) approximated that of the short women (21%). The intermediate group (156 to 168 cm) comprised 60% of the population.

Statistical analysis. Qualitative variables were analyzed by χ^2 tests. Groups A, B, and C were compared initially by a χ^2 test on 2 degrees of freedom (df), or 4 df in the case of labor pattern or mode of delivery. For many variables group A was dissimilar to group B but group B was similar to group C: in such instances the subsidiary analysis comparing group A with group B is quoted. Although all group D results are

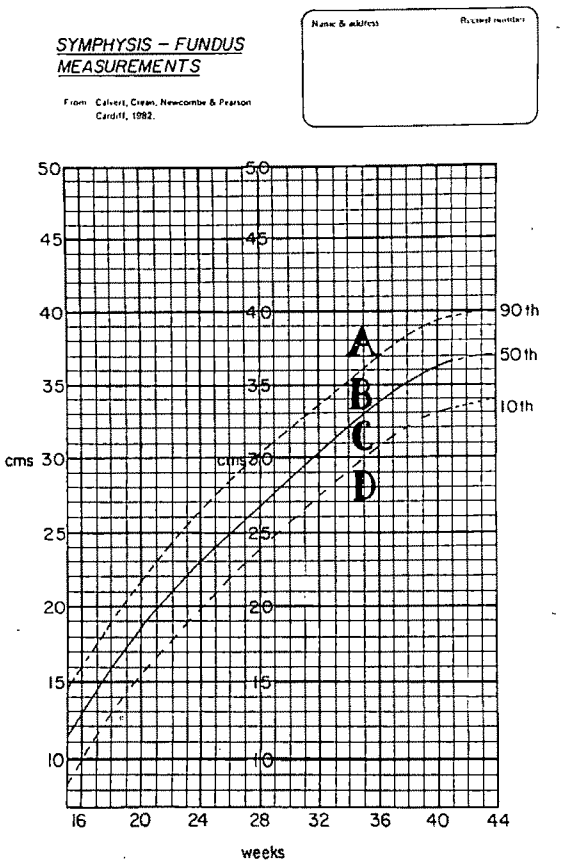

Fig. 1. Chart of symphysis-fundus height based on Cardiff data.[4]

tabulated, they were too few for statistical analysis; hence all analyses were restricted to groups A, B, and C. Birth weight and gestational age were analyzed by one-way analysis of variance.

Results

Primigravid patients (Table I). Because of the sample selection method, the distribution of symphysis-fundus heights was shifted to the right compared to published standards. There were 70 measurements in zone A, 195 in zone B, 122 in zone C, and 15 in zone D. Gestational age at delivery was slightly longer in group A than in groups B and C (Table II). Mean birth weight echeloned significantly from 3770 gm in group A, to 3410 gm in group B, and to 3170 gm in group C ($F = 51.7$, df = 2 and 384, $p < 0.001$).

The incidence of abnormal labor pattern (and/or second-stage delay) was higher in group A than in groups B and C ($\chi^2 = 29.1$, df = 2, $p < 0.001$). Similarly the incidence of operative delivery was greater in group A than in groups B and C ($\chi^2 = 31.8$, df = 2, $p < 0.001$). The corresponding rates of operative delivery for active-phase dystocia or second-stage delay in groups A, B, and C differ significantly ($\chi^2 = 44.0$, df = 2, $p < 0.001$).

The proportion of operative deliveries for which the indication was fetal distress rather than poor progress increased progressively from group A mothers with larger infants (8%), through group B (19%), to group C mothers with smaller infants (38%) ($\chi^2 = 11.03$, df = 2, $p < 0.01$).

The influence of epidural analgesia was assessed (Table III). Epidural rates were similar in group A (30%), group B (27%), and group C (25%). In the 103 primigravid women with epidural analgesia, the expected increased incidence of second-stage delay and forceps delivery was observed. The increase in incidence was similar in extent regardless of group. However, in the 284 primigravid women not receiving epidural analgesia, there was a significantly higher incidence in group A of second-stage delay ($\chi^2 = 22.52$, df = 1, $p < 0.001$) and forceps delivery ($\chi^2 = 10.40$, df = 1, $p < 0.01$) than in group B. Group C was similar to group B.

The relationship between maternal height and operative delivery for active-phase dystocia or second-stage delay was examined (Table IV). The rate of operative delivery for dystocia in the short group was 42%, in the intermediate group 30%, and in the tall group 34% (short vs. intermediate: $\chi^2 = 4.00$, df = 1, $p < 0.05$). The high rate of operative delivery for active-phase dystocia or second-stage delay in group A primigravid women applied regardless of maternal height. Group B women, with average-sized infants, had a moderate risk if they were short or intermediate in stature and a low risk if tall. Group C women, with smaller babies, had a moderate risk if short and a low risk if intermediate or tall.

Multigravid patients (Table V). There were 76 mea-

*Some patients had both active-phase dystocia and second-stage delay.

surements in zone A, 253 in zone B, 177 in zone C, and 12 in zone D. As with primigravid patients, gestational age at delivery in all groups was similar and mean birth weight decreased significantly from 3920 gm in group A to 3520 gm in group B and to 3280 gm in group C ($F = 65.5$; $df = 2$ and 503; $p < 0.001$) (Table II).

The well-known relative immunity of multigravid women to dystocia is illustrated (Table V). The pattern that emerged was similar to that found in primigravid women. Group A patients had a higher combined incidence of active-phase dystocia and second-stage delay (17%) than those in group B (5%) ($\chi^2 = 11.50$, $df = 1$, $p < 0.001$). The incidence in group C (7%) resembled that of group B. Group A patients also had a higher incidence of operative delivery (17%) than women in group B (8%) ($\chi^2 = 4.89$, $df = 1$, $p < 0.05$). The incidence in group C (5%) resembled that in group B.

Comment

Symphysis-fundus height measurement is a simple and readily communicable means of assessing fetal growth.[4] Our findings suggest that the symphysis-fundus height may also be of prognostic value with regard to pattern of labor and mode of delivery.

This study serves to quantify common sense. Group

A mothers (with larger infants) had a higher rate of abnormal labor and operative delivery than those mothers with smaller infants. This is consistent with Friedman's findings that increased fetal size is associated with a prolonged active phase and a progressive slowing in the maximum slopes of dilatation and descent.[6]

However, the extent of these problems among group A mothers was unexpected. The difference between group A mothers and mothers in groups B and C was gross for group A primigravid women and still considerable for group A multigravid women. It was even more pronounced when the confounding influence of epidural analgesia was removed. Thus group A primigravid women constitute a high-risk population, which requires delivery in a specialist obstetric unit.

Macrosomic infants have a high neonatal morbidity from delivery-associated complications. These include shoulder dystocia, meconium aspiration, birth asphyxia, and brachial plexus injury,[10] as well as the morbidity related to a higher incidence of midcavity forceps.[6] In our study 13 of 14 infants with birth weights >4500 gm were born to group A mothers. The alerting of the obstetrician to an increased risk of macrosomia before onset of labor could reduce high morbidity by earlier recourse to cesarean section.

Variable and late decelerations are of more serious import in growth-retarded fetuses,[11] who are at increased risk of intrapartum acidosis and asphyxia.[12] This study confirms that there is a progressive increase in the proportion of operative deliveries performed because of fetal distress, with decreasing size of the fetus. Antenatal fetal weight assessment by symphysis-fundus height recordings may alert the obstetrician to a higher probability of intrapartum fetal distress.

Obstructed labor remains commonplace in developing countries. Poor childhood nutrition may have led to poor maternal pelvic growth, but more recent socioeconomic improvement resulted in optimal fetal growth.[13] This considerable prevalence of cephalopelvic disproportion constitutes a major problem in association with a high domiciliary birth rate, in scattered communities, distant from specialist facilities.

There have been few antenatal screening procedures that predict for active-phase dystocia and second-stage delay. Both maternal height measurement[14, 15] and symphysis-fundus height measurement[4] are simple, reproducible, inexpensive screening tests associated with little loss of accuracy when performed by inexperienced attendents. However, although the mean height of women with major cephalopelvic disproportion was less than those without the disporportion, there was a wide range, and the individual patient's height could not be used as a predictive factor.[16]

In this study, women were grouped according to maternal height (as an indication of pelvic size) and symphysis-fundus height (as an indication of fetal size). It is important to note that the pregnancies at highest risk of dystocia were those involving larger infants (group A mothers), regardless of maternal height. Only when the infants were of average size (groups B and C) does tallness confer an advantage. Used alone, symphysis-fundus height measurement appeared to be a better discriminator than maternal height measurement with regard to the risk of dystocia. Used together, further information may be obtained on the relative risks of average-sized infants. The use of locally derived symphysis-fundus height nomograms could identify a high-risk primigravid population for early referral and result in an improved outlook for pregnant women with large babies.

Preterm labor: Stimulation of arachidonic acid metabolism in human amnion cells by bacterial products

Phillip R. Bennett, B.Sc., M.B., B.S., Mathew P. Rose, Ph.D., Leslie Myatt, Ph.D., and Murdoch G. Elder, M.D.

London, England

There is a strong association between preterm labor and infection. Some potentially pathogenic bacteria have phospholipase activity, and it has been suggested that release of phospholipase from these organisms may increase prostaglandin E_2 synthesis in amnion cells and hence initiate preterm labor. In this study we established monolayer amnion cell cultures from tissue collected at elective cesarean section at term before labor. Cells were prelabeled with tritiated arachidonic acid and then further incubated after addition of 2%, 5%, or 10% (vol/vol) filtered medium in which either group B β-hemolytic streptococcus, *Streptococcus viridans, Escherichia coli, Bacteroides fragilis,* or *Lactobacillus* had been growing. Tritiated arachidonic acid and its metabolites released by the amnion cells in these or control incubates were extracted from culture medium and separated by high-performance liquid chromatography. Addition of conditioned medium from each of the organisms with the exception of *Lactobacillus* caused an increase in overall arachidonic acid metabolism. There was an increase in the ratio of cyclooxygenase to lipoxgenase metabolism and in prostaglandin E_2 production in particular when compared to controls. The profile of arachidonic acid metabolism in amnion cells following addition of filtered bacterial medium resembled that obtained from amnion cells cultured following spontaneous labor. We suggest that abnormal bacterial colonization of the genital tract may lead to an increase in arachidonic acid metabolism in amnion cells with an increase in prostaglandin E_2 production and the consequent initiation of preterm labor. (AM J OBSTET GYNECOL 1987;156:649-55.)

Key words: Amnion, bacteria, preterm labor, prostaglandins

There is an association between preterm labor and infection. Several authors have reported a relationship between preterm rupture of membranes and maternal infection (reviewed in reference 1). Others have reported an association between preterm labor and infection with intact membranes and without signs or symptoms of infection.[2]

The commonest organism in the vagina is the *Lactobacillus,* but Goplerud et al.[3] have shown that pathogens such as *Escherichia coli, Streptococcus,* and *Bacteroides* can be isolated in small numbers from a high proportion of pregnant women. The general trend is for the numbers of these organisms to decrease as pregnancy progresses, with a resurgence during the puerperium.

Labor is associated with increased synthesis of prostaglandins by the fetal membranes, particularly the amnion.[4] These contain large amounts of arachidonic acid esterified in phospholipid pools which can be metabolized into various compounds including prostaglandins of the 2 series. Curbelo et al.[5] have measured the concentration of arachidonic acid in amnion and chorion at various stages of pregnancy and have found a concentration several times higher in amnion than in chorion, suggesting an important role for amnion in the initiation of labor. Several authors have suggested that term labor may be initiated by the activation of phospholipase enzymes that hydrolyze the esterified arachidonic acid, producing an increase in its free form and a consequent increase in prostaglandin synthesis.[6, 7] Bejar et al.[8] have shown that many pathogenic organisms may release a phospholipase enzyme, thereby activating arachidonic acid metabolism in the fetal membranes and initiating the biochemical processes of labor.

The principal cyclooxygenase metabolite of arachidonic acid in the amnion following labor is prostaglandin E_2. However, metabolism via lipoxygenase enzymes produces hydroxy–fatty acids.[9, 10] The role, if any, of these compounds in the physiology of human pregnancy has yet to be established.

In a pilot study Lamont et al.[11] have demonstrated that conditioned medium prepared from certain potentially pathogenic organisms increased the release of prostaglandin E_2, as measured by radioimmunoassay, from amnion cells in monolayer culture. We have

Arachidonic acid	58.0	57.5-58.5

Authentic tritiated or carbon-labeled standards were fractionated on a Waters fatty acid analysis column with use of a stepwise gradient of 30%, 50%, and 100% acetonitrile in 40 mmol/L of triethylamine formate (pH 3.15) at a flow rate of 1 ml/min for 25, 25, and 8 minutes, respectively. Retention times at maximum peak height and the peak widths are given.

sought to investigate the effect of these organisms on the full range of arachidonic acid metabolism by the amnion and to demonstrate dose-related changes in both cyclooxygenase and lipoxygenase products.

Material and methods

Bacteria were grown in suitable culture medium for 24 hours and then removed by filtration. Amnion cells in monolayer culture were incubated with tritiated arachidonic acid to allow incorporation into esterified pools, and the bacterial filtrate was added to them in various concentrations. Metabolites of tritiated arachidonic acid released by the amnion cells were separated by high-performance liquid chromatography and comparison made with metabolism in control cultures.

Bacterial preparations. Stock isolates of *E. coli*, Lancefield group B hemolytic streptococcus, *S. viridans*, *B. fragilis* and *Lactobacillus* were inoculated into 50 ml of suitable culture medium (Oxoid No. 2 broth or Difco Thiol liquid broth 1723/37). These isolates were incubated for 24 hours at 37° C, resulting in 10^8 organisms per milliliter of medium, and the organisms were separated by centrifugation and filtration. The conditioned medium was then stored in aliquots at −20° C until required.

Amnion cell cultures. Complete placentas and membranes were obtained from women having elective cesarean sections at term, who had not been in labor and who had had uncomplicated pregnancies, or after spontaneous labor at either term or at 30 weeks. The membranes were cut from the placental edge and the amnion was carefully peeled from the chorion by hand. The amnion, bathed in phosphate-buffered saline solution (PBS), was cut into strips 1 by 5 cm and washed twice in PBS. The strips were incubated at 20° C for 15 minutes in 0.5 mmol/L ethylenediaminetetraacetate in PBS, washed twice in PBS, and then incubated in a solution of Dispase grade II (2.5 gm/L in PBS; Boehringer) at 37° C for 45 minutes. The strips were carefully removed into 100 ml of tissue culture medium 199 (Gibco) with 10% horse serum, and the epithelial cells were liberated by vigorously shaking the container for 3 minutes. The amnion strips were then removed, an aliquot of 0.3 ml of the cell suspension was added to 0.1 ml of trypan blue, and the number of viable cells excluding the dye were counted in a hemocytometer cell. The cell concentration was then adjusted so that 10^6 cells were added to each well of a multiwell tissue plate (Flow Laboratories 76-053-05) in 2 ml of medium. This number of cells leads to a confluent homogenous cellular monolayer within 24 hours. The cells were then incubated at 37° C in an atmosphere of 5% carbon dioxide in air.

After 24 hours the culture medium was removed together with any nonadherent cells. Tritiated arachidonic acid (155 Ci/mmol; Amersham International) was added to fresh culture medium to an activity of 0.2 μCi/ml and 2 ml of this added to each culture well. After incubation for a further 24 hours (during which some metabolism of tritiated arachidonic acid takes

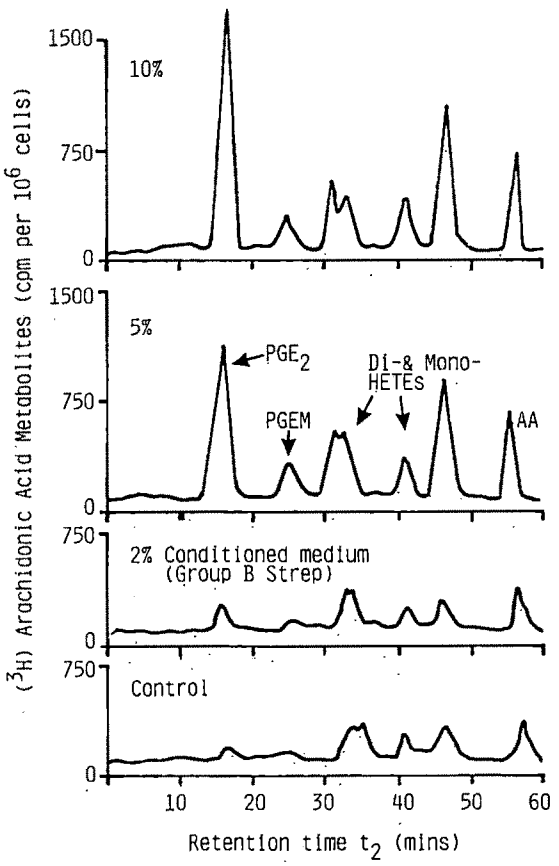

Fig. 2. Representative high-performance liquid chromatography profiles of tritiated arachidonic acid metabolites released by prelabeled amnion cells in tissue culture. Cells were obtained after elective cesarean section at term before labor. After labeling, cells were incubated with 10% *(first panel)*, 5% *(second panel)*, 2% *(third panel)*, and 0% *(fourth panel)* group B streptococcus conditioned medium.

place, but most is retained within the cells, esterified within phospholipid pools[12]), this medium was removed and added to scintillation fluid (Unisolve 1, Koch-Light Ltd.), and radioactivity was counted to allow calculation of arachidonic acid uptake by the cells. The cells were washed twice with PBS, and 2 ml of fresh culture medium with 10% horse serum without tritiated arachidonic acid but containing 2%, 5%, and 10% (vol/vol) bacterial filtrate was added to duplicate wells. Similar preparations containing 10% unused sterile bacterial culture medium were used as controls. Any change in pH of the culture fluid was adjusted for by titration with 7.5% sodium bicarbonate before use. After a further 24 hours incubation during which tritiated arachidonic acid may have been released from esterified pools and metabolized, the medium was removed and that from duplicate wells was pooled and stored at −20° C until analysis. Each well was stained with trypan blue to confirm viability of the cells.

Analysis by high-performance liquid chromatography. Each 4 ml sample of medium was acidified to a pH of 3.15 with formic acid and passed through a prepared C_{18} SepPak (Waters Associates), and the tritiated arachidonic acid metabolites were eluted into 5 ml of methyl formate. The solvent was evaporated with oxygen-free nitogen and the residue redissolved in 1 ml of 30% (vol/vol) acetonitrile in 40 mmol/L of triethylamine formate (pH 3.15). The fatty acids were then separated according to polarity with use of a high-pressure liquid chromatography system based on a reverse-phase fatty acid analysis column (Waters Associates). The initial solvent mixture was 30% acetonitrile in 40 mmol/L triethylamine formate for 25 minutes, increasing to 50% and 100% acetonitrile after 25 and 52 minutes, respectively. The solvent flow was 1 ml/min, and 0.5 minute fractions were collected for a total of 60 minutes. Each fraction was dissolved in 4 ml of scintillation fluid and the radioactivity counted in an Intertechnique SL3000 liquid scintillation counter.

We have previously reported the elution times for

Mean values ±SD are shown for three separate experiments. Significant differences from control: * = $p < 0.05$, ** = $p < 0.01$ (analysis of variance).

various arachidonic acid metabolites in this system[13] (Table I). The radioactivity present in each metabolite peak in the high-performance liquid chromatography profiles was calculated by summation. Each experiment was repeated three times, and the significance of metabolite production on addition of conditioned medium was compared with controls for each organism with use of analysis of variance.

Results

The uptake of tritiated arachidonic acid by amnion cells during 24 hours of culture was 77% ± 3.5 (mean ± SD) and was not significantly different between wells from a single tissue sample or between different samples of amnion whether cells were collected at elective cesarean section or after labor. At the end of each experiment more than 97% of the cells remained viable. Metabolism of tritiated arachidonic acid was not significantly different in those cells cultured with 10% unused sterile bacterial culture medium when compared with those cultured in tissue culture medium 199 with 10% horse serum without bacterial culture medium.

We have demonstrated release of compounds that cochromatograph with prostaglandin E_2, its metabolite 13,14-dihydro-15-keto-prostaglandin E_2, leukotriene B_4, 5-hydroxyeicosatetraenoic acid, and 12-hydroxyeicosatetraenoic acid. The compound that elutes at 46 minutes has not been identified, although on the basis of its relative lack of polarity and its acid stability, it may be a fatty acid epoxide produced by cytochrome P_{450} enzymes as has been described by Chacos et al.[14]

The high-performance liquid chromatography profile of metabolites arising from the endogenously incorporated tritiated arachidonic acid from amnion cells cultured after spontaneous labor at term (Fig. 1, *a*) was compared with the profiles from amnion cells obtained following spontaneous labor at 30 weeks (Fig. 1, *b*) or following cesarean section at term before labor (Fig. 1, *c*). There was an apparent increase in total metabolism of tritiated arachidonic acid after labor, with increased release of prostaglandin E_2 (retention time, or t_r = 16 minutes), dihydroxy–fatty acids (dihydroxyeicosatetraenoic acid) co-chromatographing with leukotriene B_4 (t_r = 34 minutes) and monohydroxy–fatty acids (monohydroxyeicosatetraenoic acids,

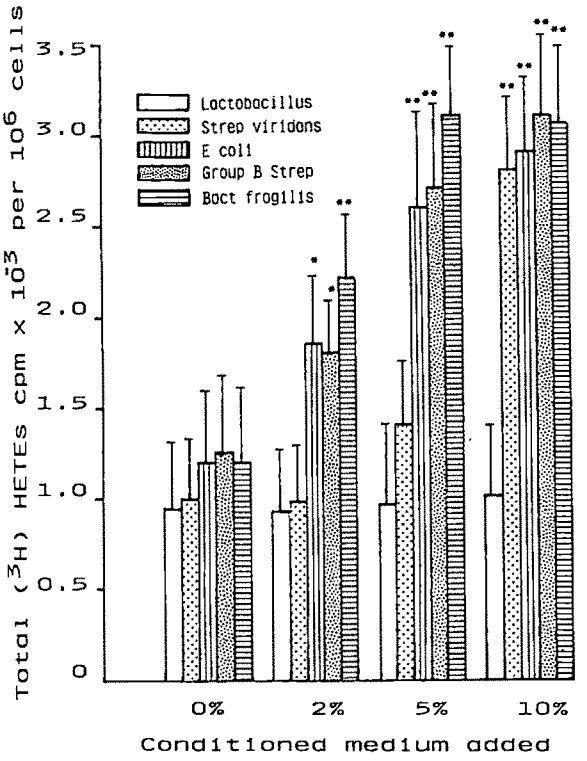

Fig. 5. Dihydroxyeicosatetraenoic and monohydroxyeicosatetraenoic acid metabolism from tritiated arachidonic acid in prelabeled amnion cells cultured after elective cesarean section at term before labor when incubated with various concentrations of conditioned medium prepared from each organism. Mean values ±SD are shown for three separate experiments. Significant differences from control: * = $p < 0.05$, ** = $p < 0.01$ (analysis of variance).

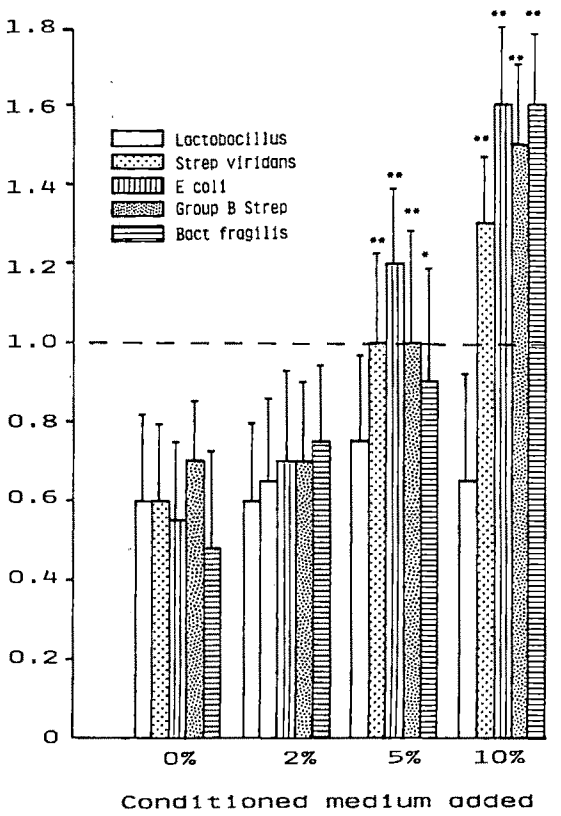

Fig. 6. Ratio of cyclooxygenase (prostaglandin E_2) to lipoxygenase (dihydroxyeicosatetraenoic acid and monohydroxyeicosatetraenoic acid) metabolism from tritiated arachidonic acid in prelabeled amnion cells cultured after elective ceserean section at term before labor when incubated with various concentrations of conditioned medium prepared from each organism. Mean values ±SD are shown for three separate experiments. Significant differences from control: * = $p < 0.05$, ** = $p < 0.01$ (analysis of variance).

t_r = 35 and 43 minutes). After either term or preterm labor there was a change in the proportion of tritiated arachidonic acid metabolism from lipoxygenase to cyclooxygenase products and therefore a relative increase in prostaglandin E_2 synthesis (Fig. 1, *b* and *c*). These changes appear to be related to the parturition process rather than the length of the pregnancy, since amnion obtained after labor at 30 weeks also had a considerable ability to synthesize prostaglandin E_2.

High-performance liquid chromatography profiles from a single experiment in which amnion cells obtained after elective cesarean section and prelabeled with tritiated arachidonic acid were incubated with increasing concentrations of group B streptococcus–conditioned medium are shown in Fig. 2. Summation of radioactivity within the peaks on the high-performance liquid chromatography profiles revealed an increase in total tritiated arachidonic acid metabolism with an apparent dose-related increase in prostaglandin E_2 production on the addition of increasing amounts of conditioned medium. Addition of 5% and 10% (vol/vol) conditioned medium prepared from all of the organisms tested except that prepared from *Lactobacillus* caused a significant increase in total tritiated arachidonic acid metabolism from endogenous sources (Fig. 3). The four active organisms had similar concentration response curves. There was an increase in metabolism via both cyclooxygenase (Fig. 4) and lipoxygenase (Fig. 5) pathways to prostaglandin E_2 and hydroxyeicosatetraenoic acids, respectively. However, the increase in cyclooxygenase metabolism was greater than the increase in lipoxygenase metabolism and the cyclooxygenase/lipoxygenase product ratio increased with addition of conditioned medium from the four active organisms (Fig. 6). Production of the prostaglandin E_2 metabolite, 13,14-dihydro-15-keto-prostaglandin E_2 (t_r = 27 minutes) was not increased despite an increase in release of prostaglandin E_2 itself. Increasing the concentration of conditioned medium to 20% caused no further increase in tritiated arachidonic acid metabolism but reduced the viability of the cells at the end of the experiment.

Comment

In this in vitro study we have used amnion cells prelabeled with tritiated arachidonic acid to replicate the in vivo source of arachidonic acid in esterified pools. Myatt et al.[9] have demonstrated that incubation with exogenous arachidonic acid causes release of prostaglandin E_2 whether the cells have been obtained before or after labor.

We have attempted to examine the full range of arachidonic acid metabolism in human amnion cells and have demonstrated metabolism by both cyclooxygenase and lipoxygenase enzymes. Our finding that the only prostaglandins produced by amnion cells are prostaglandin E_2 and its metabolite 13,14-dihydro-15-keto-prostaglandin E_2 agrees with the findings of Kinoshita and Green,[10] who were unable to demonstrate production of significant quantities of prostaglandin $F_{2\alpha}$, prostaglandin I_2, or 6-keto prostaglandin $F_{1\alpha}$ from homogenized amnion. We cannot exclude metabolism of prostaglandin E_2 to 13,14-dihydro-15-keto-prostaglandin E_2 by enzymes introduced by the horse serum. Production of 5-hydroxyeicosatetraenoic acid and 12-hydroxyeicosatetraenoic acid has been demonstrated by Kinoshita and Green[10] and Myatt et al.,[9] both of whom have confirmed their chromatographic evidence by gas chromatography and mass spectrometry.

There is an increase in arachidonic acid metabolism associated with both preterm and term labor with a change in the ratio of cyclooxygenase to lipoxygenase metabolism and a large increase in the production and release of prostaglandin E_2.[13] Similar findings have previously been reported in rabbits.[13] It has been suggested that, at term, this may be due to an increase in phospholipase enzyme activity.[6] Prostaglandin E_2 probably has a major role in the initiation of labor.

We have shown that potentially pathogenic organisms appear to cause an increase in arachidonic acid metabolism in amnion cells with an increase in prostaglandin E_2 release and a change in the ratio of cyclooxygenase to lipoxygenase metabolism, whereas *Lactobacillus*, which forms the normal flora of the vagina, does not. This effect is dose related, and the dose response curves for each organism are similar, which suggests a common mechanism. It is possible that these organisms exert this effect by release of phospholipase, since there is an increase in both cyclooxygenase and lipoxygenase metabolism. It is unlikely that these organisms release the cyclooxygenase enzyme, since Gulbis et al.[12] have demonstrated that they do not synthesize prostaglandin E_2 themselves. We have shown (unpublished work) that these organisms are unable to metabolize either cyclooxygenase or lipoxygenase products from exogenous tritiated arachidonic acid. The shift from predominately lipoxygenase to cyclooxygenase metabolism may be a consequence of the biochemistry of the amnion cell, since similar changes are seen in association with normal labor. However, it is possible that bacteria release other substances that have been shown to stimulate arachidonic acid metabolism in amnion.[16] The lack of increase in prostaglandin E_2 metabolite release despite increase in prostaglandin E_2 release is in keeping with the evidence that amnion is a minor site of further metabolism of prostaglandins in comparison with chorion and decidua, which contain larger amounts of prostaglandin dehydrogenase.[4]

This study strongly suggests a role for certain bacteria in the etiology of preterm labor in the presence of intact membranes. It explains the onset of labor in the presence of overt chorioamnionitis and may also explain the rapid onset of labor before or at term following premature rupture of fetal membranes with consequent bacterial colonization. Further work is needed to identify the bacterial agents responsible, and the role of the lipoxygenase products needs to be delineated. It should be possible, with use of a system similar to that described here, to demonstrate the effect of bacteria on the catabolism of prostaglandins in chorion and decidua. Such work would increase our understanding of the etiology of both preterm and term labor.

We are grateful to Glaxo Ltd. for providing a perinatal research fellowship for Dr. P. R. Bennett and to David Adams, Department of Bacteriology, Hammersmith Hospital, for providing bacterial isolates.

Umbilical artery Doppler blood flow studies in the preterm, small for gestational age fetus

Lesley M. McCowan, M.B., Lawrence A. Erskine, M.B., and Knox Ritchie, M.D.
Toronto, Ontario, Canada

Umbilical artery Doppler studies were performed on the day of delivery in 15 singleton preterm pregnancies. In each case the fetus was significantly growth retarded on ultrasound examination and the attending obstetrician had made a decision to deliver the patient of the infant. Eight women had severe preeclampsia, three had mild chronic hypertension, and in four there was no recognized maternal disorder. Doppler studies were analyzed by use of the pulsatility index and the A/B ratio. In 14 of the 15 cases both were markedly abnormal. Three early neonatal deaths occurred. A positive correlation was found between the degree of abnormality of the pulsatility index and A/B ratio and a poor neonatal outcome ($p < 0.001$ and $p < 0.02$). Umbilical artery Doppler studies were not helpful in differentiating between intrinsic and extrinsic causes of growth retardation but seemed to identify the pregnancy at increased risk of a poor neonatal outcome. (Am J Obstet Gynecol 1987;156:655-9.)

Key words: Doppler, umbilical artery, flow velocity waveforms, intrauterine growth retardation

Severe intrauterine growth retardation (IUGR) recognized in the second or early third trimester is uncommon and can be of extrinsic or intrinsic origin. In the former case it is most often associated with severe preeclampsia.[1] In the absence of maternal disease, an intrinsic etiology such as fetal infection or chromosome abnormality may be suspected. In as many as one third of pregnancies complicated by IUGR no predisposing cause can be identified.[2] Although the diagnosis of IUGR by ultrasound has become increasingly sensitive it is not generally useful in discerning the cause of growth failure.[3]

In early onset IUGR it can be difficult to assess fetal well-being by means of the nonstress test because the fetus is immature and the mother may be receiving medications that reduce fetal heart rate variability.[4] Furthermore, the growth-retarded fetus may have reduced heart rate variability even in the absence of acidosis.[5] It can therefore be difficult to time intervention.

The application of Doppler ultrasound to the study of fetal umbilical arterial blood flow velocity is a relatively new technique first described by Fitzgerald and Drumm[6] in 1977. Previous studies demonstrated that the end-diastolic velocity in other arterial beds is inversely related to peripheral resistance.[7] In normal pregnancy the umbilical circulation has low resistance and there is forward flow velocity throughout the cardiac cycle. As gestation advances end-diastolic velocity increases progressively, indicating a gradual fall in resistance in the umbilical-placental circulation.[8]

Previous studies have shown that substantially reduced or absent end-diastolic flow velocity in the severely growth-retarded fetus is associated with a risk of intrauterine death[8] or 5-minute Apgar score of <6.[9] The degree of flow velocity waveform abnormality, however, was not found to be related to outcome. In neither of these studies were observations made within 24 hours of delivery.

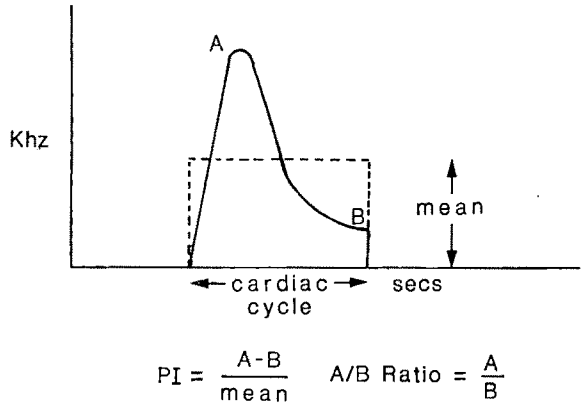

Fig. 1. Schematic representation of a flow velocity waveform showing methods of calculation of pulsatility index and A/B ratio.

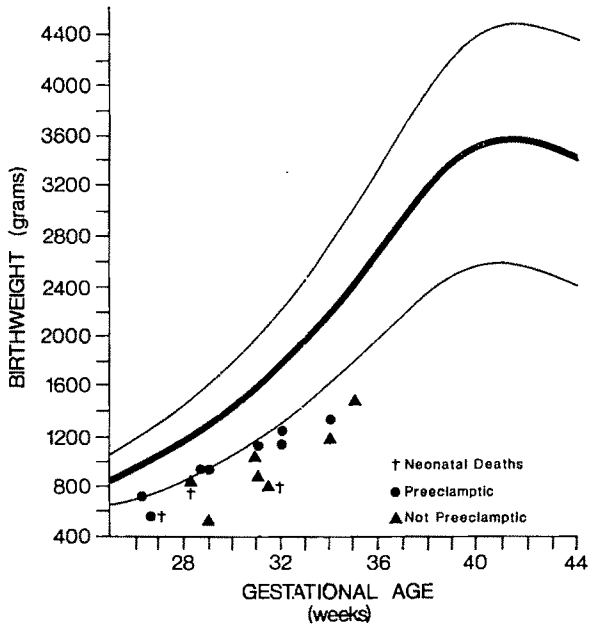

Fig. 2. Birth weight distribution of the neonates. Normal range (mean ± 2 SD) is shown.

The principal aims of this study were to determine whether the umbilical arterial flow velocity waveform in fetuses with early onset of IUGR could be related to fetal condition at birth and to determine whether this waveform was useful in differentiating between intrinsic and extrinsic causes of growth retardation.

Patients and methods

Umbilical artery Doppler flow velocity studies were performed in 15 preterm patients with severe IUGR suggested by ultrasound examination and confirmed at birth. In all cases examinations were performed on the day of delivery. None of the Doppler study results were made known to the attending physician and did not influence patient management.

Patients. The mean age of patients studied was 28 years (range 21 to 39). Nine patients were nulliparous. Eight patients were diagnosed as having preeclampsia and three as having mild chronic hypertension. In four instances there was no identifiable maternal abnormality.

Methods. Examinations were performed with a portable continuous wave instrument (Bach-Simpson, London, Ontario, Canada) with a 4 MHz probe (power output at the transducer surface 80 mW/cm^2). Most examinations were performed at the bedside with the patient in a semirecumbent position, and when the characteristic auditory signal of the umbilical artery was obtained it was recorded by a tape recorder (Sony Professional Walkman). These data were played back through a spectral analyzer (Advanced Technology Laboratories, Bothell, Washington) and a hard-copy printout was made to include at least 10 waveforms for subsequent secondary analysis.

Evidence from peripheral vascular studies suggests that end-diastolic velocity reflects peripheral resistance and several different indices have been used to express changes in resistance. Methods used to analyze umbilical artery time velocity waveforms have been described in detail.[8] The most useful appears to be the pulsatility index because it can quantify results adequately when diastolic flow velocity is absent or reversed. The A/B ratio is also useful and simple to calculate but has the disadvantage of becoming infinity when flow velocities are absent or negative when they are reversed. Both ratios were computed in the present study; the method of calculating them is shown in Fig. 1. Ten consecutive waveforms were analyzed and the mean result was compared with our previously established normal range.[8] In an attempt to identify the fetus that might be at increased risk of a poor outcome, an arbitrary pulsatility index value of 2 was chosen. All values above this level had absent or reversed end-diastolic flow velocity. Outcomes were compared in infants with pulsatility index values above and below 2.

To perform a similar analysis for the A/B ratio, a value of >100 was chosen because this included all cases with absent end-diastolic flow velocity. One case with reversed end-diastolic flow velocity was also included in this group.

All of the patients had reliable menstrual dates and had an ultrasound examination in the first or second trimester.

Usher and McLean[9] charts were used to classify the birth weight of the infants studied. Growth retardation was diagnosed when birth weight was 2 SD below the mean.

The results were subjected to statistical analysis that

Table I. Maternal and neonatal characteristics of the patients studied

included the calculation of correlation between variables and the Mann-Whitney one-tailed nonparametric test.

Results

Thirteen patients were delivered electively by cesarean section. On two occasions this was done for maternal indications (worsening preeclampsia) and the remaining 11 for presumed serious fetal compromise.

The mean birth weight at delivery was 981 gm (range 570 to 1510 gm) and the mean gestational age 30.7 weeks (range 26 to 35 weeks). There were three early neonatal deaths. In all cases birth weight was at least 2 SD below the mean (Fig. 2). Further details of the neonates including Apgar scores, umbilical artery pH, and the need for intubation at birth and the antepartum pulsatility index values are shown in Table I. Outcome refers to condition at discharge from hospital. A good outcome was defined as an infant that was well and appeared neurologically normal at the time of discharge from the hospital. A poor outcome was defined as neonatal death, chromosomal abnormality, or evidence of a neurological problem at the time of discharge from hospital. By these criteria nine infants had good outcomes and six had poor outcomes. No newborn infant had a hematocrit >60%.

Successful Doppler studies were possible in all of the patients. In 14 of the 15 cases studied, the pulsatility index and A/B ratios were substantially outside the normal range. The values obtained for the last pulsatility index and A/B ratios are shown in Figs. 3 and 4. The A/B ratio in the single patient with reversed end-diastolic flow velocity is reported as >8.

Neonatal outcome was examined in all cases. There was no correlation between umbilical artery pH, Apgar scores, or the need for intubation at birth and the degree of abnormality of either the pulsatility index or A/B ratio. The six patients with an abnormal pulsatility index value had either absent (five cases) or reversed (one case) end-diastolic flow velocity. This group included the three infants that died in the early neonatal period and a case of trisomy 21. In one case congenital viral infection was suspected because of hepatosplenomegaly, hyperbilirubinemia, intracerebral calcification, and abnormal muscle tone. There was one apparently healthy infant. Five of these six cases therefore had a poor outcome. The infants with poor outcomes had significantly higher pulsatility index values than those with a good outcome ($p < 0.001$, one-tailed Mann-Whitney test).

There were eight infants with an A/B value of >100. This group included the three that died, the infant with trisomy 21, and one with suspected congenital viral infection. Three infants were apparently normal. Thus five of the eight had a poor outcome. The infants with poor outcomes had significantly higher A/B values than those with good outcomes ($p < 0.02$, one-tailed Mann-Whitney test).

Only three infants in the series were acidotic at birth, with an umbilical artery pH <7.20. Two of the three subsequently died. The surviving infant (Case No. 1) had a normal umbilical artery end-diastolic flow velocity and the low cord pH probably resulted from acute maternal blood loss resulting from a ruptured liver in a woman with severe preeclampsia.

The first of the three infants that died (Case No. 2) was born at 26.7 gestational weeks, developed severe respiratory distress syndrome, and died of respiratory complications and renal failure. The second (Case No. 10) was born at 31.4 gestational weeks, had a pul-

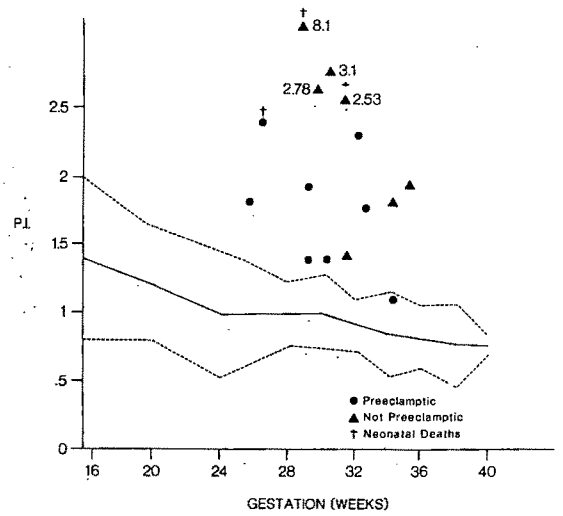

Fig. 3. Last pulsatility index measurements. Normal range (mean ± 2 SD) is shown.

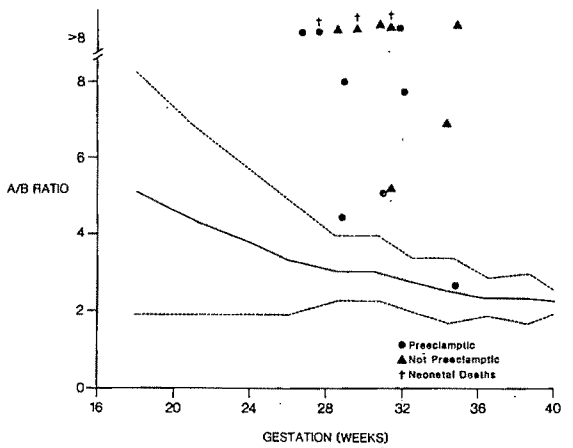

Fig. 4. Last A/B ratio measurements. Normal range (mean ± 2 SD) is shown.

monary hemorrhage at 3 days, and an intracerebral hemorrhage was found at autopsy. The third (Case No. 14) was born at 28.3 gestational weeks, developed respiratory distress syndrome and had a pulmonary hemorrhage, and was found to have intracerebral hemorrhage at autopsy. Each of the three babies that died was thrombocytopenic at birth and this is the subject of a further study.

All of the patients had a nonstress test performed. It was reactive in four and there was a good outcome in each case. Eleven patients had a nonreactive nonstress test with poor fetal heart rate variability. Five of the mothers were receiving magnesium sulfate infusions and six were receiving no medication. Three of the 11 had low umbilical pH (<7.20) at birth, including the two infants with very abnormal pulsatility index values who subsequently died and one whose mother was found to have a ruptured liver. Of the remaining

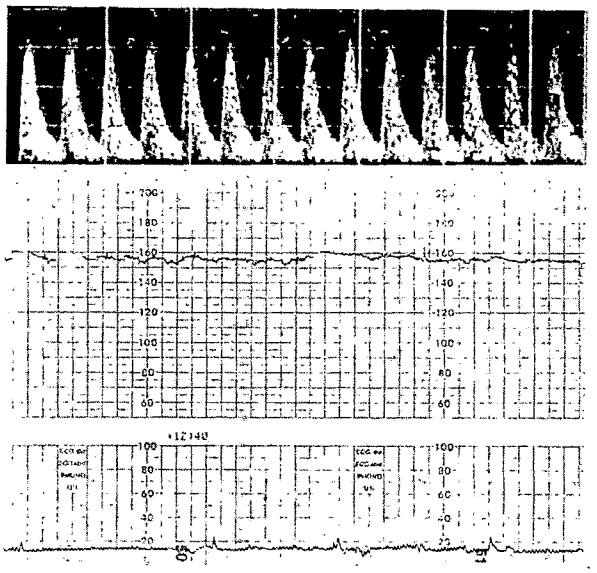

Fig. 5. Case No. 3, demonstrating a nonreactive nonstress test, moderately abnormal umbilical artery Doppler study (pH 7.34), and a good outcome.

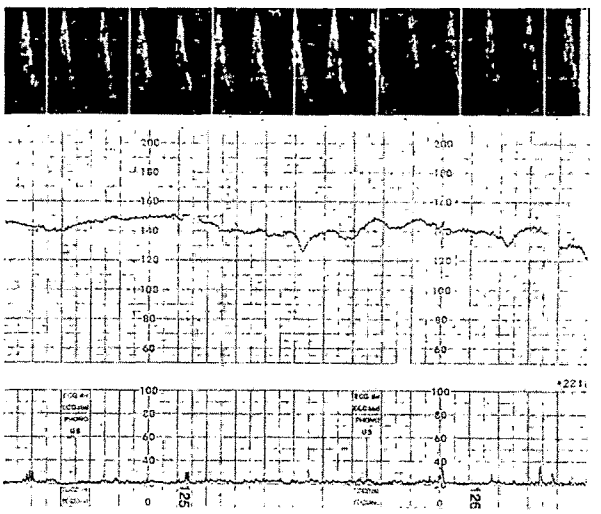

Fig. 6. Case No. 10, demonstrating a nonreactive nonstress test and abnormal umbilical artery Doppler study (pH 7.15) associated wtih birth asphyxia and neonatal death.

eight infants, six were in good condition at birth and two had only minor cord blood gas abnormalities. Figs. 5 and 6 demonstrate examples of nonreactive nonstress tests with poor variability, Doppler study results, and umbilical artery pH values. The nonstress test was nonreactive in both but there was a marked difference in the cord flow velocity waveform. The fetus with the higher pulsatility index value was severely compromised at birth.

Comment

Severe early onset growth retardation is relatively rare and it is difficult for one center to collect a large

series for study. In this small series, although 14 of 15 had abnormal umbilical artery flow velocity waveforms, the majority (nine) had a good outcome. When the pulsatility index was very abnormal, however, there was a highly significant risk of poor neonatal outcome, with five of six infants with pulsatility index values >2 having a poor outcome.

When an A/B ratio of greater than 100 was chosen (absent or reversed end-diastolic flow velocity), less accurate prediction of fetal risk was achieved inasmuch as three of these eight infants had a good outcome; however, there was still a significant association between high A/B ratio and poor outcome. This small difference between the two ratios in predicting outcome may arise because the pulsatility index differentiates between waveforms even when end-diastolic flow velocity is absent. This is because of an assessment of the area under the waveform, whereas the A/B ratio becomes infinity in all such cases.

Earlier studies of Erskine and Ritchie[8] and Trudinger et al.[10] demonstrated that an abnormal umbilical artery waveform was associated with a risk to the fetus but this risk could not be quantified, possibly because in most cases at least several days elapsed between Doppler study and delivery. In the present study all of the patients were examined on the day of delivery, usually only a few hours before birth.

The decision to deliver by cesarean section was independently made by the attending physician in the knowledge that the fetus was severely growth retarded and had a fetal heart tracing that was nonreactive or had poor variability. The interpretation of these tracings was complicated because five of the 11 nonreactive traces were in preeclamptic patients treated with magnesium sulfate, which is known to depress fetal heart rate variability.[4] Only three of the 11 had a low umbilical artery pH at birth. Aside from maternal medication, these results would support the work of Henson et al.[5] who found that a group of growth-retarded fetuses had significantly less fetal heart rate variation than control fetuses matched for gestational age and that such reduced variability was not necessarily related to fetal acidosis.

Our results will need to be confirmed in a larger series, but in the growth-retarded preterm fetus the degree of abnormality of the flow velocity waveform appears to be a more sensitive predictor of fetal outcome than a nonreactive nonstress test or a finding of reduced fetal heart rate variability.

In a woman with severe preeclampsia and a ruptured liver (Case No. 1), the fetus had a normal pulsatility index and A/B ratio. This is the first time we have seen a normal waveform in a severely growth-retarded preterm fetus and we are unable at present to explain this finding.

In four mothers there were no underlying maternal disorders. This group of patients is difficult to manage antenatally because one is always concerned about the risk of chromosomal or congenital anomalies or congenital viral infection. In this group two infants appear to be completely normal, another has trisomy 21, and one has a possible congenital viral infection. All four infants had very abnormal pulsatility index values; thus the pulsatility index was not helpful in differentiating between intrinsic and extrinsic causes of fetal growth retardation. This observation confirms that made previously by Trudinger and Cook.[11]

In summary, in the preterm growth-retarded fetus, umbilical artery flow velocity waveforms seem to carry information concerning fetal condition in utero that is more difficult to predict by other current methods such as the nonstress test. The technique, however, does not appear to allow differentiation between intrinsic and extrinsic causes of IUGR.

Adjuvant therapy for Stage I uterine sarcoma

Peter G. Rose, M.D., John G. Boutselis, M.D., and Larry Sachs, Ph.D.
Columbus, Ohio

A retrospective evaluation of adjuvant therapy in 64 patients with Stage I sarcoma was undertaken. A combination of operation and adjuvant radiation was compared with operation alone. A decreased recurrence of both pelvic and distant tumor was noted for endometrial sarcoma but not for leiomyosarcoma treated with adjuvant radiation. A Cox regression analysis showed a trend for improved survival, but the results were not statistically significant. Survival after vaginal cuff recurrence and treatment with radiation therapy (two patients) or combined radiation and chemotherapy (one patient) is reported. Seven patients received adjuvant chemotherapy with Adriamycin-based regimens. Chemotherapy alone did not statistically decrease recurrence in this small sample. (Am J Obstet Gynecol 1987;156:360-2.)

Key words: Uterine sarcoma, adjuvant therapy, radiation therapy, chemotherapy

Uterine sarcoma is rare, accounting for only 1% to 3% of uterine cancers. Its management is controversial and its rarity has hindered prospective studies. Because of the high recurrence rate of early stage disease (50% to 80%)[1-3] various adjuvant therapies have been used. Evaluations of these treatment regimens have relied extensively on retrospective studies that often span many years during which staging and treatment techniques have varied. We undertook such a retrospective study to determine whether adjuvant therapy affected the rate of recurrence in Stage I uterine sarcoma.

Methods

One hundred three patients with uterine sarcoma treated by The Ohio State University Gynecology Oncology Service from 1940 to 1984 were reviewed. At the time of diagnosis or surgical exploration, disease was not limited to the uterine corpus in 39 patients and they were excluded from this analysis. The remaining 64 patients were classified according to a modified uterine sarcoma nomenclature adopted by the gynecologic oncology group.[4] Patients were evaluated according to primary treatment regimen, and outcomes were statistically analyzed by the χ^2 test or Fisher's exact test.

Results

Sixty-four patients with Stage I uterine sarcoma included patients with carcinosarcoma (n = 17), endometrial stromal sarcoma (n = 10), fibrosarcoma (n = 1), leiomyosarcoma (n = 18), and mixed mesodermal sarcoma (n = 18). Patients were treated by operation (n = 32), radiation (n = 9), operation and radiation (n = 16), or operation and chemotherapy (n = 7). Adjuvant radiation treatment consisted of preoperative brachytherapy (n = 6), preoperative brachytherapy and teletherapy (n = 1), postoperative teletherapy (n = 7), and preoperative brachytherapy and postoperative teletherapy (n = 2). External radiation consisted of whole pelvic radiation, 4000 to 5000 rads in 200 rad fractions, over a period of 4 to 5 weeks. Brachytherapy consisted of a colpostat and tandem implant, delivering 3000 to 5000 rads to point A.

Chemotherapy consisted of Adriamycin-based regimens for 12 courses or until recurrence. Patients received vincristine, Adriamycin, and cyclophosphamide (VAC) (n = 4), cisplatin, Adriamycin, and cyclophosphamide (n = 1), Adriamycin and cyclophosphamide (n = 1), and Adriamycin, vincristine, and dacarbazine (DTIC) (n = 1).

In patients treated with operation or radiation alone, the recurrence rates were high, 75% and 77%, respectively. Treatment with operation and radiation or with operation and chemotherapy produced better results, with recurrence rates of 56% and 43%, respectively.

Statistical evaluation of treatment modality and subsequent recurrence was performed for all uterine sarcomas, endometrial sarcomas, and leiomyosarcomas. Recurrence of endometrial sarcoma was decreased for operation and radiation (five of 11) versus operation alone (22 of 27) ($p < 0.04$). The combination of operation and adjuvant chemotherapy was not statistically better than operation alone. Recurrence after radiation or operation alone (27 of 33) was significantly higher ($p < 0.05$) than after combined operation and adjuvant therapy (radiation or radiation and chemotherapy) (six of 13).

Addition of adjuvant treatment, radiation or che-

motherapy, did not improve the survival or the time to recurrence for leiomyosarcoma.

When all uterine sarcomas were evaluated, improved outcome was seen only when combinations of operation and radiation or operation and chemotherapy were compared with operation or radiation alone ($p = 0.05$).

Despite decreased recurrence rates after adjuvant radiation therapy in patients with endometrial sarcoma, 45% had recurrent disease. The site of recurrence (pelvic versus distant) was not statistically different in patients treated with operation alone (45%) than in those treated by combined operation and radiation (40%). Radiation technique did not affect the recurrence rate in this series.

A Cox regression analysis of survival of patients with endometrial sarcoma, with correction for age at diagnosis and treatment at recurrence, showed a trend but no statistical improvement in this sample size.

Comment

The finding that the combination of operation and radiation is more effective than operation alone in preventing recurrent endometrial sarcoma but not leiomyosarcoma is in agreement with results of previous authors.

Belgrad et al.[5] reported on 34 patients, 16 of whom had Stage I disease. For all stages, radiation therapy resulted in an improved 2-year survival, except for those with leiomyosarcoma. Treatment results for patients with Stage I disease were not analyzed separately, however, and whether this radiation was adjuvant or therapeutic is unclear.

Gilbert et al.[6] analyzed 105 patients with uterine sarcoma, 57 of whom had Stage I disease. Although the authors favored adjuvant radiation therapy, only four patients with Stage I disease received primary operation and radiation therapy and no statistics were reported.

Vongtama et al.[7] studied 104 cases of Stage I or II uterine sarcoma and noted, in 87 patients with Stage I disease, a trend for improved survival with adjuvant radiation, but the results were not significant. In their series, pelvic radiation decreased local failure rates from 55% to 26%. No specific form of radiation therapy, whole pelvic or intracavitary, offered superior results.

Salazar et al.[8] reported on 18 patients with Stage I mixed mesodermal sarcoma. Of 12 patients treated with operation and radiation, only 50% had recurrences, in contrast to all six of the patients treated with operation alone ($p < 0.05$).

More recently, Sorbe[9] reported on 87 patients with uterine sarcoma, 59 of whom had Stage I (47) or II (12) disease. In 18 patients receiving adjuvant radiation therapy pelvic recurrences decreased, but there was no statistical improvement in survival.

Inasmuch as the addition of radiation in this study statistically decreased recurrence, both pelvic and distant, it would seem to be effective in treating local nodal disease and vaginal cuff recurrence before distant spread. Two patients in our study who had vaginal cuff recurrence were treated with external radiation and survived 20 and 206 months; one died of recurrent sarcoma and the other of a cerebrovascular accident. A third patient with recurrence that was limited to the vaginal cuff and treated with external radiation and chemotherapy (cyclophosphamide, vincristine, Adriamycin, and DTIC for 10 courses) is alive 52 months after recurrence. Buschbaum et al.[10] reported survival of a patient with mixed mesodermal sarcoma treated with radiation for vaginal cuff recurrence.

Because of the small number of patients treated prophylactically with chemotherapy, its role in Stage I uterine sarcoma is not defined by this study. In view of frequent distant recurrence and the proved although limited effectiveness of chemotherapy in advanced disease,[11, 12] there is great interest in prophylactic chemotherapy if Stage I disease exists. Buschbaum et al.,[9] reporting on 10 patients treated with VAC, noted an 80% 3- to 7-year survival. Two surviving patients had more than 10 mitoses per 10 high-power fields and no prior reports had documented survival in such cases. In nonrandomized studies, Hannigan et al.[13] reported no benefit of VAC chemotherapy and Barter et al.[14] reported no improvement with Adriamycin, VAC, or methotrexate, Adriamycin, and cyclophosphamide in a small series of patients. The gynecologic oncology group prospectively randomized 156 patients with Stage I or II uterine sarcoma treated with Adriamycin every 3 weeks for eight courses versus no additional therapy.[15] No improvement was noted for the Adriamycin-treated group but patients varied in their treatment with respect to adjuvant pelvic radiation.

The low response rate to chemotherapy in patients with established disease requires analysis of a large series of patients to prove that prophylactic therapy is beneficial. Whether the clinical benefit will outweigh the toxicity remains doubtful.

As with other malignancies, adequate staging of uterine sarcoma is important in determining appropriate therapy. More recently, the significance of pelvic (35%) and para-aortic (14.3%) lymph node metastasis in Stage I disease has been appreciated.[16] As with other sarcomas, hematogenous dissemination is rapid, with pulmonary metastasis the most common site of disease at autopsy.[17] Some authors advocate peritoneal cytologic washings and omentectomy as part of routine staging.[4] Although these pathologic variables are part of

our present staging protocol, they are not included in this series or in any other series in the literature.

A prospective study of postoperative pelvic radiation in Stage I and II mixed mesodermal sarcoma (Gynecologic Oncology Group 75-RTOG 8402) is in progress and is projected to be completed in 1994. The present data support adjuvant radiation for uterine sarcomas, except leiomyosarcomas, but only through prospective collaborative studies can our understanding and treatment of these rare malignancies be improved.

Clinicopathologic study of eight cases of uterine body cancers associated with endometriosis interna (uterine adenomyosis)

Takashi Hayata, M.D., and Yoshiro Kawashima, M.D.
Hamamatsu, Japan

Among 30 cases of uterine body cancers, in eight cases (Stage IA, two cases; Stage IB, six cases) uterine adenomyosis was demonstrated microscopically. The age range was from 46 to 66 years with a median of 56. When these eight cases were compared with the 12 cases of Stage I endometrial cancer without adenomyosis, there was no difference in either menstrual history or family history, although past histories of hypertension and diabetes mellitus were found in these eight cases. The mean obesity index was 127 in eight cases and 116 in 12 cases. Seven of these eight cases were pure tubular adenocarcinoma. From the standpoint of early myometrial infiltration of the endometrial cancer, these eight cases not only provided a good model to survey early endometrial cancer but also suggested a common stimulus, such as estrogen, in both endometrial cancer and uterine adenomyosis. (Am J Obstet Gynecol 1987;156: 663-6.)

Key words: Endometrial cancer, adenomyosis, clinicopathologic study

Endometriosis interna (adenomyosis), which is very painful in menstruating women and results in severe dysmenorrhea, was studied clinicoendocrinologically. In a study of 30 cases of endometrial cancer at our hospital, we found uterine adenomyosis in specimens from eight of the 20 cases of early endometrial cancer. These uterine cancers that contained microscopic adenomyosis were studied clinicopathologically and were compared with 12 cases of endometrial cancer without adenomyosis.

Material and methods

Details of eight cases of endometrial cancer with adenomyosis are shown in Table I. The age range was 46 to 66 years, with a median of 56. Parity and gravidity averaged four and two, respectively. The chief complaint in five of the eight cases was genital bleeding. All cancers were classified as Stage I according to the criteria of the International Federation of Gynecology and Obstetrics (two were Stage IA and six were IB).

Results

Menstrual history. There were no significant findings in regard to age at menarche or at marriage. Menstrual cycles were regular in four cases and irregular in four cases. One patient with regular menses and two with irregular menses had dysmenorrhea. Age at menopause in five cases ranged from 45 to 53; the other three patients were premenopausal (Table II). The duration from menarche to menopause, to last delivery (or pregnancy), and to operation is shown in Table III. When one shows the time to menopause as ~, the time from menarche to menopause or the duration of menstruation ranges from 28 to ~41 years (average of ~36). The period between menopause and operation ranged from 2 to 15 years (average of 8 years). The period from last delivery (or pregnancy) to operation was between 23 (17 for pregnancy) to 35 (33 for pregnancy) [average of 27 (or 23 for pregnancies)].

Medical history (Table IV). In three of the eight cases hypertension was an associated finding and there was one case of diabetes mellitus. In the other 12 cases of Stage I uterine cancer and without adenomyosis, hypertension and diabetes mellitus were not found.

Family history (Table V). In two of the eight cases, a father and an elder brother had diabetes mellitus. In five cases first- or second-pedigree relatives have died of cancer. On the contrary, in the 12 cases of endometrial cancer without adenomyosis, there were no cases of diabetes mellitus or cancer elsewhere in the body.

Obesity index (Table VI). The obesity index was calculated by the formula: body weight × 100 divided by (height − 100) × 0.9. The obesity index score in eight cases of Stage I uterine corpus cancer with adenomyosis ranged from 100 to 147 (average = 127). In 12 cases of Stage I uterine corpus cancer without adenomyosis the average score was 116. In 30 cases of Stage I cervical cancer with a similar age range the obesity index score was 106.

Histopathologic findings (Table VII). The histologic

8	155	51	103
Mean	149	55	127

Obesity index calculated as: $\frac{\text{Weight} \times 100}{(\text{Height} - 100) \times 0.9}$

Table VII. Histologic types of carcinoma

Case No.	Age (yr)	Type of cancer	Endometrial background	Adenomyotic glandular tissue
1	46	Tubular adenocarcinoma	Proliferative endometrium	Proliferative endometrium-like
2	55	Tubular (comedo-like) adenocarcinoma	Proliferative endometrium	Proliferative endometrium-like
3	48	Tubular adenocarcinoma	Atrophy	Proliferative endometrium-like
4	66	Papillotubular adenocarcinoma	Day 20 endometrium	Day 19 endometrium-like
5	60	Tubular adenocarcinoma	Proliferative endometrium	Proliferative endometrium-like
6	54	Tubular adenocarcinoma	Proliferative endometrium with focal cystic glandular hyperplasia	Proliferative endometrium-like
7	56	Tubular adenocarcinoma	Day 27 endometrium	Day 23 endometrium-like
8	59	Tubular adenocarcinoma	Proliferative endometrium	Proliferative endometrium-like

type of the presented cases of corpus cancer was well-differentiated tubular adenocarcinoma with the exception of papillotubular adenocarcinoma in case No. 4. The histologic features that preceded these corpus cancers were proliferative endometrium in five cases, atrophy in one, and secretory endometrium in two. Adenomyotic glandular epithelium demonstrated a proliferative endometrium–like pattern, except in two cases with secretory endometrium–like adenomyotic glandular tissue. Histologic examination of the ovaries revealed five cases with a corpus albicans and two with a corpus luteum. There was one case of ovarian endometriosis (Case No. 1) without any malignant transformation pattern.

Comment

More cases of microscopic adenomyosis in cases of uterine corpus cancer have been reported than one might estimate. Giammalvo and Kaplan[1] stated that among 120 cases of endometrial cancer (all were adenocarcinomas, with exclusion of carcinosarcomas, autopsy cases, and cases without a description of the clinical stages), 40 (33%) contained microscopic adenomyosis. Marcus[2] found 60 cases of adenomyosis in 100 endometrial cancers in comparison with 39 in 100 cases in the control group. In 39 of 60 cases of adenomyosis associated with endometrial cancer, endometrial hyperplasia was also demonstrated, which is significantly different from the seven among 39 cases in the control group.

The fact that eight of our own 30 cases of endometrial cancer associated with adenomyosis were all Stage I leads us to consider the possibility that these cases could be good models in which to follow the myometrial infiltration of corpus cancer in its early phase.

Endometrial hyperplasia as a histologic background of corpus cancer, such as in those cases in the report of Marcus,[2] was not found, except for the one case with focal cystic glandular hyperplasia. In other words examination of the endometrium before the cancer was diagnosed in seven of eight cases revealed normal histologic features.

Our own 100 cases of adenomyosis (microscopic or clinical) up to the present have shown no instances of malignant transformation of the adenomyotic glandular epithelium histologically.

That two of the eight cases described here had atypical glandular epithelium (a definite diagnosis such as adenomyotic glandular tissue was not possible because of the lack of endometrial stroma) suggests the possibility of an early myometrial infiltrating pattern of endometrial cancer.

In any case data such as histologic findings and clinical history (menstrual history, medical history, family

history, and obesity index score) suggest that some common stimuli such as estrogen promote both uterine corpus cancer and adenomyosis.

Type-specific streptococcal antibodies in amniotic fluid

Barry M. Gray, M.D., Janet D. Springfield, M.P.H., and Hugh C. Dillon, Jr., M.D.
Birmingham, Alabama

Type-specific antibodies against group B streptococcal and pneumococcal capsular antigens were measured in 68 amniotic fluid samples from healthy women between 16 and 20 weeks of pregnancy. Mean antibody levels ranged from 0.13 to 0.61 μg/ml, with few samples having >1 μg/ml against any antigen. The role of antibodies in protection against intrauterine infection is discussed. (AM J OBSTET GYNECOL 1987;156:666-9.)

Key words: Group B streptococci, pneumococci, antibodies, amniotic fluid

Amniotic fluid normally contains low but measurable amounts of immunoglobulins, mostly of the IgG class.[1] Immunoglobulin levels of all classes are fairly constant throughout gestation, with a decrease in IgG at term, probably because of changes in amniotic fluid volume.[2] The role of specific antibodies in amniotic fluid has yet to be explored, although there is some evidence for both specific and nonspecific opsonization of *Escherichia coli* and group B streptococci by term and preterm amniotic fluid.[3] In this study we offer quantitative data on amniotic fluid levels of type-specific antibody against the four major polysaccharide antigens of the group B streptococci and eight common capsular types of *Streptococcus pneumoniae.*

Methods

Amniotic fluid samples were collected from women attending the Prenatal Genetics Clinic of the University of Alabama at Birmingham in December 1984, according to methods previously described.[4] Indications for amniocentesis included maternal age ≥35 years, family history of congenital anomalies, and history of obstetric complications. No cultures for carriage of group B streptococci or pneumococci were done, and no sera were available for study. Sixty-eight clear fluid samples were selected randomly from otherwise healthy women between 16 and 20 weeks of pregnancy. The amniotic fluid specimens were initially processed in the Laboratory of Medical Genetics; the centrifuged supernatant fluids were stored at −20° C until used for antibody determinations.

Antibodies to group B streptococci and pneumococcal polysaccharide antigens were measured quantitatively by enzyme-linked immunoassay methods modified from those described for group B streptococci type II.[5] Group B streptococci type Ib, II, and III polysaccharides were prepared by mutanolysin extraction and purified by chromatography, essentially as described by De Cueninck et al.[6] The type Ia polysaccharide was prepared by sonication in cold 2.5% trichloroacetic acid followed by separation of group and type antigens over a Sepharose 6B column.[7] Purified pneumococcal polysaccharides of types 1, 3, 4, 6, 9, 14, 19, and 23 were obtained from Lederle Laboratories, Pearl River, New York, and from Eli Lilly & Company, Indianapolis, Indiana. Each polysaccharide was coupled to polylysine[8] and dispensed in 300 μl volumes into plastic microtiter wells (Dynatech Laboratories, Alexandria, Virginia). The wells were incubated overnight at room

temperature, washed with deionized water, filled with 0.1% bovine serum albumin, and refrigerated until use.

Amniotic fluid was added to the wells in 50 μl volumes and diluted with 250 μl of phosphate-buffered saline–Brij (0.05 mol/L phosphate, 0.1 mol/L sodium chloride, and 0.05% Brij, Aldrich Chemical, Atlanta, Georgia), pH 7.4. After incubation for 3 hours at room temperature, unbound antibody was washed out with deionized water. β-Galactosidase conjugated goat antihuman $F(ab')_2$ (Southern Biotechnology Associates, Inc., Birmingham, Alabama) was diluted 1:500 in a phosphate-buffered saline–Brij buffer of greater ionic strength (0.55 mol/L sodium chloride and 0.05 mol/L phosphate, pH 7.4) and added to the wells in 300 μl volumes. After 2 hours of incubation the wells were again washed, and 300 μl of enzyme substrate was added to each well. The substrate was o-nitrophenyl-β-D-galactopyranoside (Sigma Chemical Company, St. Louis, Missouri) diluted to 1 mg/ml in 0.01 mol/L Tris, pH 7.5, containing 0.01 mol/L concentrations of sodium chloride, magnesium chloride, and 2-mercaptoethanol. The change in optical density was read after 20 minutes at 414 nm with an eight-channel photometer (Titertek Multiskan, Flow Laboratories, McLean, Virginia). Results, expressed as absorbance units, were converted to micrograms of antibody protein per milliliter by calculation from a standard curve consisting of IgG measured by quantitative precipitation for antibody against a pneumococcus type 19 antigen.[5] Although the anti-$F(ab')_2$ conjugate detected antibodies of all classes, most (80%) amniotic fluid antibody at 16 to 20 weeks' gestation is of the IgG class[1] and values were assumed to be equivalent in micrograms to the amount of IgG in the standard. The linear portion of the curve corresponded to 0.03 to 1.42 μg/ml of amniotic fluid, on the basis of 50 μl samples. Further sample dilutions were made as necessary, and all assays were done in duplicate.

Results

Antibody levels in 68 amniotic fluid samples are presented in Table I. Mean levels were 0.18 to 0.40 μg/ml against group B streptococcal antigens; the highest levels were against type II, followed by types Ib, III, and Ia. Antibodies against pneumococcal polysaccharides averaged 0.13 to 0.61 μg/ml, the highest being those for types 4 and 14. Levels ranged as high as 1 to 3 μg/ml, but very few samples had >1 μg/ml.

It was of some interest to note that within a given patient there was a tendency to have little or no antibody against any group B streptococcal type or to have antibodies against multiple types. This is illustrated in Fig. 1, counting the number of types for which a patient had greater than the mean antibody level. The distribution was far more uniform (Pearson χ^2 (4 df) = 31.8, $p < 0.0001$). The 31/68 patients who had no antibody greater than the mean accounted for most of the deviation (their contribution to the total χ^2 = 22.3), while the frequency of those with antibody against two or three types was lower than expected. No such striking distribution was seen with respect to antibodies against pneumococcal polysaccharides.

Comment

Amniotic fluid appears to play a role in protecting the fetus from bacterial infection by a variety of mechanisms.[9] Certain organisms, including *Escherichia coli*, may be inhibited by a zinc-dependent peptide[9] in the absence of complement and phagocytes. The group B streptococci are inhibited little or not at all by amniotic fluid alone,[10-12] but specific as well as nonspecific opsonic activity has been demonstrated in a chemiluminescence assay in the presence of human peripheral neutrophils.[3] Unlike gram-negative organisms, which may be lysed by antibody and complement activation, the group B streptococci require antibody, complement, and phagocytosis to effect killing.[13]

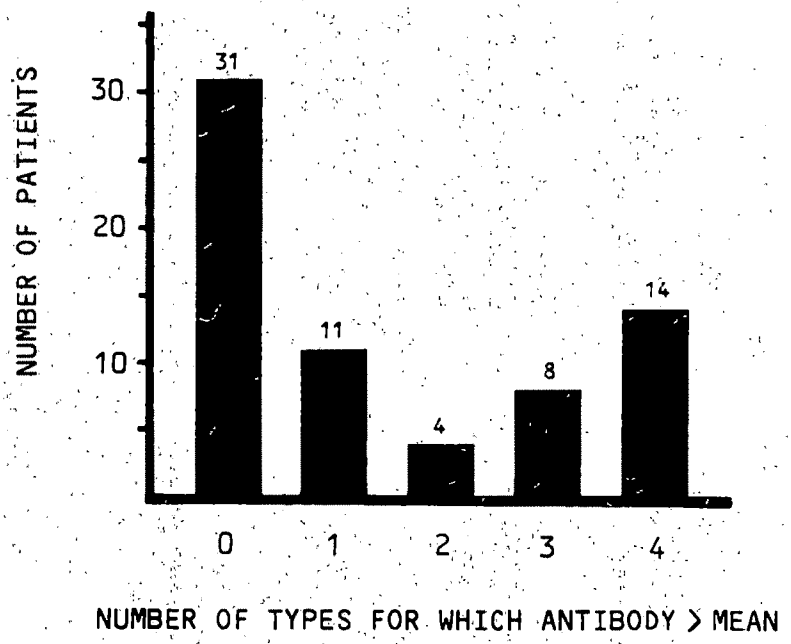

Fig. 1. Sixty-eight amniotic fluid samples were tested for antibody against group B streptococci types Ia, Ib, II, and III. The figure shows the distribution of patients according to the number of types for which the antibody level was greater than the mean. The proportion of patients with antibody greater than the mean against four types or against no types was greater than expected (see Results). No such type-related distribution was seen for antibody against the eight pneumococcal types tested.

In previous studies we found the prevalence of serum IgG against group B streptococci types Ia, II, and III quite low, with only about 6% of women at delivery having >2 μg/ml.[5, 14] Carriers of group B streptococci were more likely to have antibody against one or more types, whereas noncarriers rarely had antibody. Although culture data were not available from patients in the present study, antibody levels were less than the mean for all four types in nearly half the specimens. To get a broader picture of antibody prevalence against gram-positive capsular polysaccharides, we also measured levels against common pneumococcal types. The rarity of amniotic infection due to pneumococci is not likely to be explained by the presence of antibody, which was as low as that against group B streptococci; rather it probably reflects differences in epidemiology of this respiratory pathogen. The presence of antibody to group B streptococci, in serum or in amniotic fluid, may have a protective role, but the vast majority of individuals, with little or no antibody, are at no apparent risk for perinatal disease. On the other hand, antibody present at the time of infection may not always be adequate to forestall invasion.[5]

It is nonetheless quite reasonable to propose that the presence in amniotic fluid of even small amounts of type-specific antibody may be beneficial. Unless rupture of the membranes has occurred, the numbers of group B streptococci gaining access to the amniotic cavity are likely to be very small. An average antibody concentration of 0.4 μg/ml multiplied by 500 to 1000 ml of fluid is a considerable amount. Complement may be available in amniotic fluid and certainly is available in perfused tissues. Neutrophils are not a regular constituent of amniotic fluid but are often present as the result of a maternal inflammatory response.[15] Intrauterine invasion by bacteria may be hindered enough to prevent infection of the fetus. This is consistent with the observation that infants delivered of mothers with group B streptococcal amnionitis may escape infection even though they are heavily colonized at birth.[16] These hypotheses remain to be tested, and other explanations have yet to be explored.

We wish to thank Drs. Wayne and Sara Finley and the staff of the Laboratory of Medical Genetics and Drs. Richard Davis and Cynthia Brumfield of the Department of Obstetrics and Gynecology. Dr. David B. Pritchard provided purified group B streptococcal polysaccharides.

Luteal function in ectopic pregnancy

Corinne J. Hubinont, M.D., Christine Thomas, M.D., and Jean F. Schwers, M.D.
Brussels, Belgium

Human chorionic gonadotropin, estradiol, progesterone, and 17-hydroxyprogesterone have been measured in the serum of 46 patients with ectopic pregnancy. All these hormones were significantly lower than in normal pregnancy. Unruptured ectopic pregnancy differed from the ruptured state by a lower serum human chorionic gonadotropin concentration, a slower human chorionic gonadotropin increment, a higher incidence of metrorrhagia, and an earlier diagnosis. The concentration of estradiol, progesterone, and 17-hydroxyprogesterone in the serum of patients with ectopic pregnancy was lower than could be expected from the decrease of human chorionic gonadotropin, often lower than in a normal luteal phase. It is suggested that, as long as ultrasonography fails to show an intrauterine pregnancy, the simultaneous determination of serum human chorionic gonadotropin and progesterone could aid in the early diagnosis of ectopic pregnancy and in the improvement of subsequent fertility; to that regard any progesterone level below 15 ng/ml in the presence of detectable amounts of human chorionic gonadotropin is highly suggestive of either a threatened abortion or an ectopic pregnancy, whatever the gestational age. (Am J Obstet Gynecol 1987;156:669-74.)

Key words: Ectopic pregnancy, corpus luteum, human chorionic gonadotropin, estradiol, progesterone, 17-hydroxyprogesterone

The low level of serum human chorionic gonadotropin in patients with ectopic pregnancy is well documented, but very little attention has been paid to the evaluation of luteal function in these patients. It is now established that the serum human chorionic gonadotropin concentration is significantly reduced in cases of ectopic pregnancy[1-4] and that repeated human chorionic gonadotropin determinations show a very slow increase in ectopic pregnancy as compared with normal pregnancy.[5,6] As regards the luteal function it has only been mentioned by Milwidsky et al.[7] that the ser-

7	217 (n = 10)	1452† (n = 11)	8,200 (n = 29)
8	183 (n = 6)	857† (n = 7)	11,820 (n = 29)

Number of samples is shown in parentheses.
*Completed weeks from last menstrual period.
†$p < 0.001$ for t test between ruptured and unruptured ectopic pregnancies.

um progesterone level is lower than that in normal pregnancy.

Some investigators[6] have shown that repeated human chorionic gonadotropin determinations would be helpful in cases of suspected ectopic pregnancy, but no one has ever suggested that the simultaneous determination of human chorionic gonadotropin and ovarian steroids could also provide some useful information when ultrasonography fails to demonstrate an intrauterine pregnancy.

In the present investigation, human chorionic gonadotropin, estradiol, progesterone, and 17-hydroxyprogesterone have been measured in the serum of 46 patients with ectopic pregnancy and compared with normal values. The differences between ruptured and unruptured ectopic pregnancy were also analyzed as regards to hormone levels and incidence of uterine bleeding.

Material and methods

Forty-nine consecutive and pathologically verified ectopic pregnancies were studied retrospectively. All blood samples had been collected beween 3 and 10 weeks and always before operation. Three ovarian pregnancies were excluded from the present study; of the remaining 46 tubal pregnancies 18 (39%) were ruptured at the time of operation. One to five blood samples were collected from each patient. Serum human chorionic gonadotropin, estradiol, progesterone, and 17-hydroxyprogesterone were measured by specific radioimmunoassays.

The normal range for each of these hormones was previously determined from some 800 serum samples collected between 3 and 42 weeks of gestation (nearly 200 between 3 and 10 weeks) and processed by the same radioimmunoassay. The gestational age is expressed as completed weeks from last menstrual period.

Since the data from hormone assays usually show a log normal distribution rather than a normal distribution, statistical parameters such as mean, SD, t test, and correlations were calculated on a logarithmic basis. The lower and upper limits of the normal range were set at the tenth and ninetieth percentiles, respectively. The χ^2 tests were performed with the use of the correction for small numbers.[8]

Results

Human chorionic gonadotropin. Nearly all human chorionic gonadotropin values fell below the normal range, except for the samples collected during the fourth week of pregnancy. As shown in Table I, mean human chorionic gonadotropin levels were significantly lower in unruptured than in ruptured ectopic pregnancies ($p < 0.001$). The human chorionic gonadotropin slope from 5 to 9 weeks also showed a difference between these two groups, with a mean value of 23 ng/day for the former and 43 ng/day for the latter. In normal pregnancy the mean increase of human chorionic gonadotropin during that period of gestation is linear and reaches 500 ng/day.

Steroids. Levels of ovarian steroids were generally below the normal range (Figs. 1 to 3) but the difference between ruptured and unruptured ectopic pregnancies was not as evident as for human chorionic gonadotropin. For the samples collected at 7 and 8 weeks a significant positive correlation exists between human chorionic gonadotropin and progesterone ($r = 0.6384$, $p < 0.01$ for 20 df) and between human chorionic gonadotropin and estradiol ($r = 0.4469$, $p < 0.05$ for 18 df) but not between human chorionic gonadotropin and 17-hydroxyprogesterone.

Although a significant correlation did exist between human chorionic gonadotropin and progesterone the decrease of the latter was apparently more important than that of the former; in other words the progesterone concentration in ectopic pregnancy seemed lower than that expected in a normal pregnancy with a similar human chorionic gonadotropin level. In order to assess

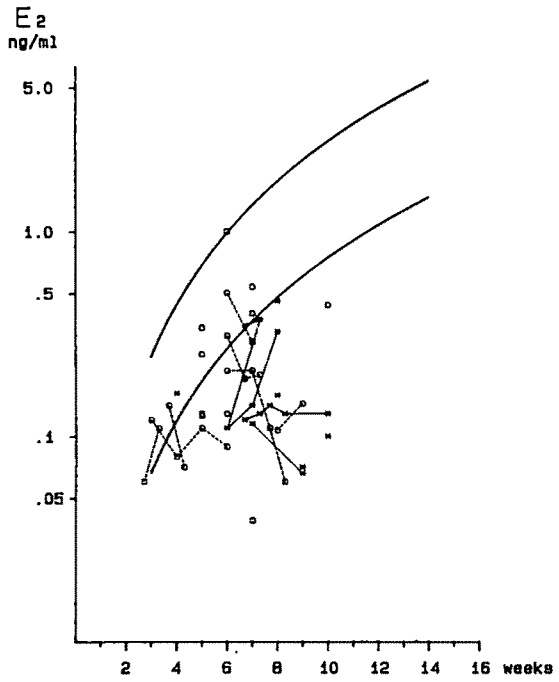

Fig. 1. Serum estradiol *(E_2)* concentration in patients with ectopic pregnancy (o for unruptured ectopic pregnancies and * for ruptured ectopic pregnancies). The *solid lines* represent the limits of the normal range (tenth and ninetieth percentiles).

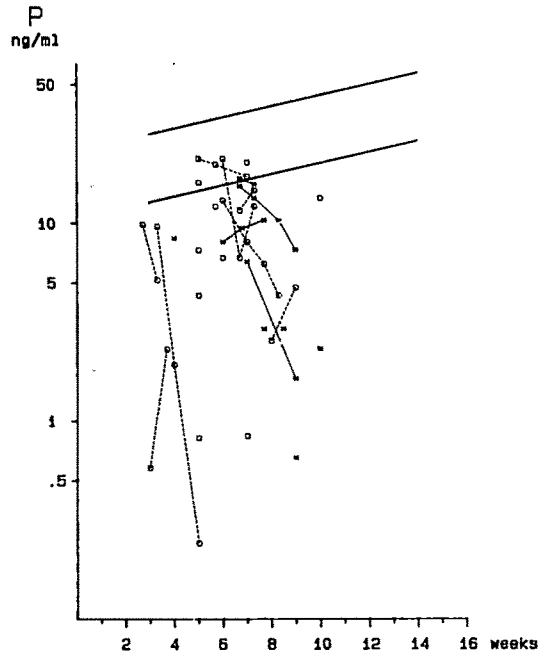

Fig. 2. Serum progesterone *(P)* concentration in patients with ectopic pregnancy. For further details refer to legend of Fig. 1.

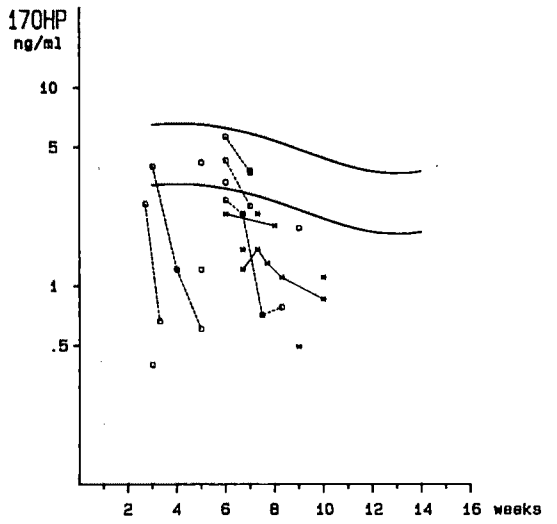

Fig. 3. Serum 17-hydroxyprogesterone *(17OHP)* concentration in patients with ectopic pregnancy. For further details refer to legend of Fig. 1.

that assumption, ectopic and normal pregnancies were paired for human chorionic gonadotropin, and progesterone levels were compared. As shown in Table II, in 20 of 21 cases a normal pregnancy could be found with a human chorionic gonadotropin value that matched within 4%; in the last case (121 versus 133 ng/ml) the difference reached 10%. The mean values of human chorionic gonadotropin were 580 and 583 ng/ml, respectively, for ectopic and normal pregnancies, and the paired t test did not show any significant difference between these two groups of patients. On the other hand, the progesterone concentration reached a mean value of only 7.8 ng/ml in ectopic pregnancy versus 23.6 ng/ml for the control group. As shown by the paired t test that difference was highly significant ($t = 5.622$, $p < 0.001$ for 20 df).

The data for the other steroids are also presented in Table II. For estradiol the mean values were 0.178 and 0.488 ng/ml ($t = 5.738$, $p < 0.001$ for 20 df), respectively, and for 17-hydroxyprogesterone they were 1.70 and 4.97 ng/ml ($t = 6.509$, $p < 0.001$ for 11 df).

The discrepancy between human chorionic gonadotropin and ovarian steroids was not specific for ectopic pregnancy; indeed similar results were obtained in a group of 20 patients with spontaneous abortion.

Comment

The results of serum human chorionic gonadotropin assays are in agreement with those of recent investigations.[1-6] Serial human chorionic gonadotropin determinations show a sensitivity of nearly 100%. Therefore the diagnosis of ectopic pregnancy may be ruled out when human chorionic gonadotropin is not detectable. Sandvei et al.[2] have reported, in a study of 100 cases,

Table II. Human chorionic gonadotropin, estradiol, progesterone, and 17-hydroxyprogesterone in the serum of patients with ectopic pregnancy of 7 or 8 weeks and in the sera of normal pregnancies paired for human chorionic gonadotropin concentration

Table III. Predictive value of serum progesterone determination in early pregnancy

Pregnancy outcome	*Serum progesterone*					
	<15 ng/ml		*>15 ng/ml*		*Total*	
Normal		64		514		578
Abnormal						
Ectopic	9		2			
Abortion	41	54	21	30		84
Blighted egg	3		7			
Hydatidiform mole	1		–			
Total		118		544		662

on three patients with undetectable serum human chorionic gonadotropin levels. These were "devitalized" ectopic pregnancies. In the present investigation, only one patient had a human chorionic gonadotropin level that decreased from 10 ng/ml to undetectable; the diagnosis of tubal pregnancy was made fortuitously when laparoscopy and a microsurgical procedure were performed to manage a problem of infertility.

The "vitality" of ectopic pregnancy that eventually ruptures is probably better than that of those that do not rupture. This could explain both the higher hormone secretion and the trophoblastic proliferation leading to the tubal rupture.

As could be expected, luteal insufficiency is also associated with ectopic pregnancy. Most serum estradiol, progesterone, and 17-hydroxyprogesterone levels are lower than the mean normal values, with more than 80% of the data below the tenth percentile (Figs. 1, 2, and 3). Despite the presence of detectable amounts of human chorionic gonadotropin, which is presumed to stimulate the corpus luteum, the concentrations of these steroids were even lower than those in a normal luteal phase. The luteal insufficiency observed in ectopic pregnancy cannot be explained by the sole decrease of human chorionic gonadotropin. Indeed Fig. 4, which is derived from the data presented in Table II, shows that the concentration of ovarian steroids in ectopic pregnancy reaches only one third of

that observed in normal intrauterine pregnancy although both groups have been paired for identical human chorionic gonadotropin levels.

Such low values probably reflect the fact that, even in early pregnancy, a significant part of the so-called "ovarian steroids" is no longer secreted by the corpus luteum but by the trophoblastic tissue,[9] the vitality of which is critically reduced in ectopic pregnancy. However, other mechanisms may be involved in the reduction of steroid concentrations; for instance, one may suggest that insufficient stimulation of corpus luteum by human chorionic gonadotropin since the early stages of ectopic pregnancy induces its precocious senescence.

In cases of ectopic pregnancy the subsequent fertility of the patient is closely related to the time of the diagnosis. Therefore any investigation that could help an early diagnosis should be taken into consideration, particularly in patients at risk. To that regard the systematic quantitative determination of serum human chorionic gonadotropin levels is certainly a good precaution. The effectiveness of the human chorionic gonadotropin assay could be improved by serial determination as suggested by Kadar et al.[6] Indeed the interpretation of a single result may be difficult, especially in the case of an unreliable date of last menstrual period. Another way to improve an early diagnosis of ectopic pregnancy could be the simultaneous determination of human chorionic gonadotropin and progesterone. In normal pregnancy the progesterone level remains quite stable during the first weeks[10]; therefore a single result can be interpreted, even in the absence of an accurate gestational age, while this is not true for human chorionic gonadotropin. In the present investigation 84% of the first progesterone determinations fell below the tenth percentile (15 ng/ml). To assess the predictive value of the progesterone assay for an early diagnosis of ectopic pregnancy and threatened abortion, a prospective study was performed during a period of 15 months. During that period human chorionic gonadotropin and ovarian steroids were measured systematically at the first visit in 662 patients with a gestational age of ≤8 weeks. The correlation between progesterone concentration and pregnancy outcome is presented in Table III. As shown in that table a cutoff at 15 ng/ml gives a specificity of 88.9% (514 of 578) and a sensitivity of 64.7% (54 of 84). The predictive value for a progesterone level >15 ng/ml (percent of normal outcomes when progesterone concentration is normal) reaches 94.4% (514 of 544); that for a progesterone level <15 ng/ml (percent of abnormal pregnancies when progesterone concentration is subnormal) stands at 45.7% (54 of 118). The results of that prospective study confirm that the determination of the serum progesterone concentration in early pregnancy is a valuable tool for the screening of ectopic pregnancies and spontaneous abortions. However, it should be emphasized that human chorionic gonadotropin assays cannot be replaced by progesterone assays; the former remains essential to assume the presence of trophoblastic tissue somewhere in the patient, and the latter only provides some quantitative information on the "vitality" of the pregnancy. It is also clear that as soon as an intrauterine pregnancy can be visualized by ultrasonography such a policy is no longer necessary as regards the diagnosis of an ectopic pregnancy.[5, 11] However, hormonal investigations are of value in cases of threatened abortion or other abnormal bleeding.[12, 13]

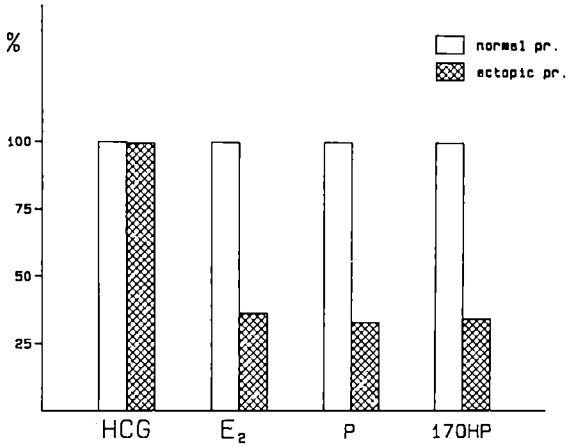

Fig. 4. Mean concentration of human chorionic gonadotropin *(HCG)*, estradiol *(E_2)*, progesterone *(P)*, and 17-hydroxyprogesterone *(17OHP)* in the serum of patients with normal *(open column)* and ectopic *(hatched column)* pregnancy. Samples have been paired for human chorionic gonadotropin concentration. Results are presented as percent of the geometric mean from the control group.

Pregnancy-induced changes in the fibrinolytic balance: Evidence for defective release of tissue plasminogen activator and increased levels of the fast-acting tissue plasminogen activator inhibitor

Margaret Gore, M.D., Susan Eldon, A.B., Kenneth F. Trofatter, M.D., Ph.D., Seng-Jaw Soong, Ph.D., and Salvatore V. Pizzo, M.D., Ph.D.

Durham, North Carolina, and Birmingham, Alabama

Pregnancy is accompanied by an increased risk of thromboembolic disease. One contributing factor to such disease in the nonpregnant patient is disordered fibrinolysis. It has been suggested that defective fibrinolysis may occur in pregnancy, but this defect has been poorly characterized. In the present stucy of 52 women with normal pregnancies and 56 nonpregnant control women, we found a marked change in levels of releasable tissue plasminogen activator in pregnant women beginning in the first trimester. Whereas nonpregnant women demonstrated releasable levels of tissue plasminogen activator of 0.74 ± 0.15 IU/ml of plasma, in the pregnant women the amount released was only 0.06 ± 0.02 IU/ml of plasma ($p < 0.01$). These levels were observed beginning in the first trimester. Levels of the recently described fast-acting tissue plasminogen activator inhibitor increased significantly throughout pregnancy. Values ranged from 8.40 ± 0.27 IU/ml of plasma in the first trimester to 9.92 ± 0.09 IU/ml of plasma in the third trimester ($p < 0.05$) compared with the level of 8.46 ± 0.19 IU/ml of plasma in nonpregnant subjects. These data suggest that alterations both in releasable tissue plasminogen activator and in the fast-acting tissue plasminogen activator inhibitor contribute to the physiologic hypercoagulable state of pregnancy. (AM J OBSTET GYNECOL 1987;156:674-80.)

Key words: Fibrinolysis, tissue plasminogen activator, tissue plasminogen activator inhibitor, pregnancy

Uncomplicated pregnancies are accompanied by hypercoagulability and an increased risk of thromboembolic disease.[1, 2] Estimates of the incidence of thromboembolic disease in pregnant women have varied between 0.3 and 14 per 1000 pregnancies.[3, 4] Thrombosis is rare in the first trimester, and most events are noted in the last trimester. Interestingly, some patients demonstrate a thrombotic event in the face of a hemorrhagic tendency. In one study 46% of the pregnant women who had pulmonary emboli also demonstrated a hemorrhagic diathesis.[3] Complications included pelvic and perineal hematomas and placenta previa. A number of coagulation alterations are observed during pregnancy, including altered platelet function and increased plasma levels of fibrinogen and factors VII,

VIII, IX, X, and XII.[1,2] Moreover, increased fibrinogen catabolism has been documented by a rise in plasma fibrin monomer complexes and split products.[1,2] It has been suggested that this hypercoagulability is a normal consequence of the need to protect the placental implantation site.[2]

Whereas levels of coagulation factors increase in pregnancy, deranged fibrinolysis may also contribute to the hypercoagulable state.[1,2] The nature of this altered balance is uncertain because the studies were performed with integrative assays of fibrinolysis such as the euglobulin lysis time or fibrin plate assay. Considerable advances in fibrinolytic research have been made during the last few years, and greatly improved and more specific assays of fibrinolysis are available.[5-8] It is necessary, in addition to measuring baseline plasminogen activator levels, to stimulate release of tissue-type plasminogen activator from blood vessels. Little of this substance is found in the unperturbed circulation, yet the level of releasable tissue plasminogen activator bears the closest correlation to a thrombotic disorder.[5-8]

More recently, alterations in a newly discovered fast-acting tissue plasminogen activator inhibitor have been described in conjunction with thromboembolic diseases.[7,8] This inhibitor is the major plasma inhibitor of tissue plasminogen activator as well as urokinase. The remaining plasma proteinase inhibitors, such as α_2-macroglobulin, α_1-antiproteinase, antithrombin III, and α_2-plasmin inhibitor, inactivate tissue plasminogen activator at a relatively slow rate. Since tissue plasminogen activator clears from blood with a half-life of only 2 minutes, such inhibitors would have little opportunity to bind tissue plasminogen activator.[9] A recent study has suggested an increase in the plasma inhibitory capacity for tissue plasminogen activator, particularly in the third trimester of pregnancy.[10]

Finally, alterations of vitamin K–dependent protein C have been associated with altered fibrinolysis in several families with idiopathic thromboembolic disease and in experimental models.[11] Levels of this protein, however, remain normal in pregnancy, even in the third trimester.[12] In the present study we have focused on measurement of tissue plasminogen activator and its inhibitor. In all, plasma from 52 pregnant women, 56 nonpregnant women, and 62 men were compared by means of a new and more specific fibrin-stimulated tissue plasminogen activator assay.[6,7]

Material and methods

Subjects. The pregnant population consisted of 52 women with no evidence of preeclampsia, eclampsia, or overt thromboembolic disease. All subjects had reached at least 10 weeks' gestation before the study was begun. The population's mean age was 24.5 ± 5.3 years (SD). The only basis for excluding a subject was refusal to participate in the study or inability to obtain a blood sample. The control group consisted of 56 nonpregnant women with a mean age of 26.3 ± 4.8 years. None of these women had a history of thromboembolic disease, and none was receiving hormonal supplements. None had been pregnant within 1 year of the study. In addition, 62 normal men were included for comparison. Blood was taken from all subjects after informed consent was obtained, in accordance with a protocol approved by the Human Experimentation Committee at Duke University Medical Center. Previous studies demonstrated no differences in releasable tissue plasminogen activator[5-7] on the basis of blood group, race, age, or sex. In the present study data were not stratified for blood group or race. The age difference in study and control subjects was <2 years and was not further analyzed.

Fibrinolytic assays. Blood samples were obtained before and after 5 minutes of venous occlusion at a pressure midway between systolic and diastolic, as previously described.[5-7] The samples were quick-frozen in dry ice–ethanol and kept at −80° C until assayed. The plasma was subjected to euglobulin fractionation and then reacted with plasminogen and the plasmin substrate D-valine-leucine-lysine-*p*-nitroanilide hydrochloride, as previously reported.[5-7] The assay was modified by addition of 10 μl of fibrin monomer (3.75 mg/ml) to each 500 μl assay sample. Fibrin monomer was prepared as previously described.[13] Substrate hydrolysis was monitored by absorbance at $\lambda = 405$ nm. A tissue plasminogen activator standard curve was constructed with a National Institute of Biological Standards control tissue plasminogen activator preparation (No. 83/517), generously supplied by Dr. Henry Berger of the Wellcome Research Laboratories. Fast-acting tissue plasminogen activator inhibitor was assayed as previously reported[7,8] by titration of the plasma inhibitor with purified tissue plasminogen activator (to a final theoretical plasma concentration of 10 IU/ml). In this assay the concentration of one component (tissue plasminogen activator) of the bimolecular reaction must be held constant in order to estimate the second component (tissue plasminogen activator inhibitor).[7] This method may result in an underestimation of levels if the amount of tissue plasminogen activator added is insufficient to react with all of the inhibitor. As previously reported,[10] this assay generally has been performed by addition of tissue plasminogen activator at a concentration of 2 IU/ml of plasma. We recently modified the assay by the addition of 5 IU/ml of plasma.[7] Under these conditions higher apparent levels of the inhibitor were noted.[7] In the present study assays were initially performed by addition of tissue plasminogen activator at a concentration of 5 IU/ml of plasma. When these same plasma

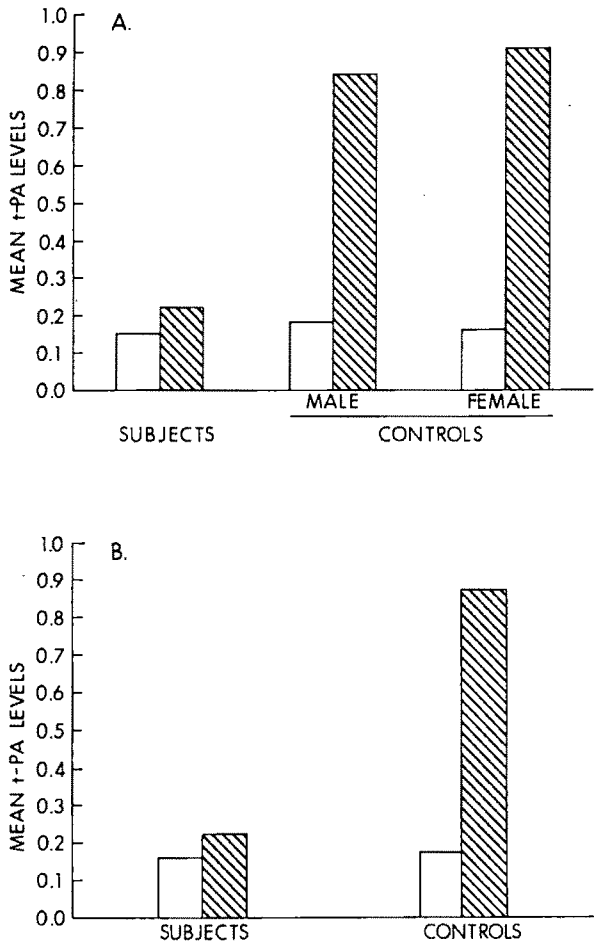

Fig. 1. Comparison of mean tissue plasminogen activator levels for pregnant women and control subjects. The *open bar* represents preocclusion levels of activator and the *hatched bar*, the postocclusion values. In *A* the controls are divided by sex, whereas in *B* a comparison is made to all 118 control subjects.

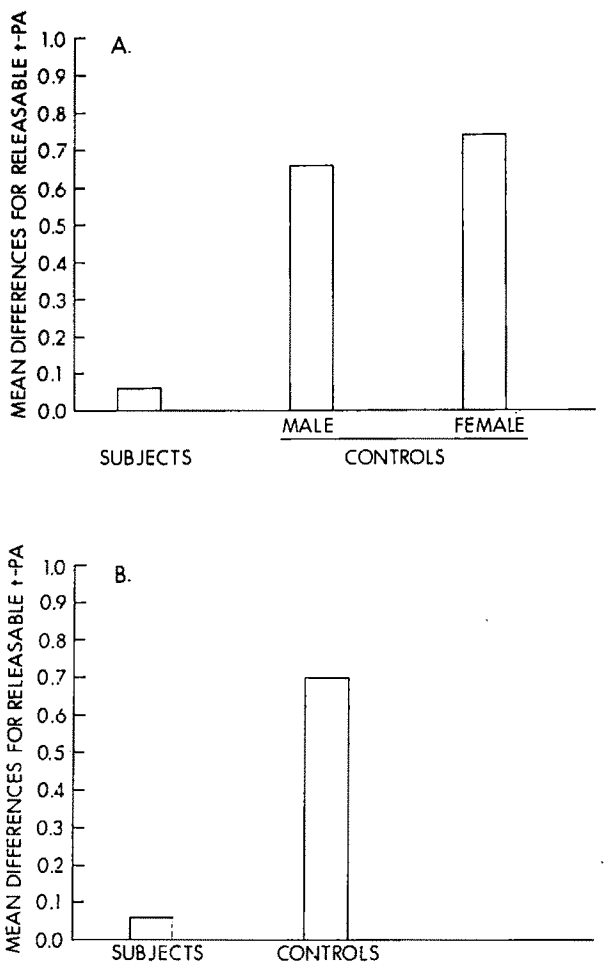

Fig. 2. Comparison of releasable tissue plasminogen activator levels for pregnant women and control subjects. *A* compares the pregnant subjects with men and nonpregnant women separately. In *B* comparison is made with all 118 control subjects.

samples were titrated with 10 IU/ml of plasma, the apparent inhibitor concentrations were often more than twofold higher but appeared to have reached a plateau. For this reason we have performed the assay by addition of tissue plasminogen activator at a concentration of 10 IU/ml of plasma to each sample of plasma. The same concentration of tissue plasminogen activator must be added to each sample or the assumptions for a bimolecular reaction mechanism will not be met.[7]

Statistical analysis. Student's *t* test, the paired *t* test, and Duncan's multiple range test were used in the statistical analyses, as indicated in the footnotes to the tables. For proper adjustment of significance level in the comparisons of all pairs of means involving more than two groups, Duncan's test was used. Mean values are reported along with the standard error of the mean, and all the statistical tests used were based on a two-tailed test.

Results

Tissue plasminogen activator. The mean values for plasma activator levels are presented in Fig. 1. Preocclusion levels of activator were essentially equivalent. By contrast, there was a significant difference ($p < 0.01$) between postocclusion levels of activator when pregnant women were compared with either nonpregnant women or men. Some of the activator present in plasma is urokinase-like, and subtraction of preocclusion from postocclusion plasma levels more clearly reflects release of vascular stores of tissue plasminogen activator.[5-7] Data on releasable tissue plasminogen activator are presented in Fig. 2.

These data were then analyzed for statistical significance (Table I). As anticipated, there was no significant difference between men and pregnant or nonpregnant women when preocclusion data were analyzed, with the mean values ranging from 0.16 ± 0.02 to 0.18 ± 0.02

Table I. Comparison of levels of plasminogen activators in pregnant women, nonpregnant women, and men

Measurement	*Pregnant women (n = 52) (IU/ml)*	*Control subjects*		*Comparisons**
		Men (n = 62) (IU/ml)	*Nonpregnant women (n = 56) (IU/ml)*

†Mean ± SE.

IU/ml of plasma. When postocclusion data were compared values in the pregnant women (0.22 ± 0.03 IU/ml of plasma) were some fourfold lower than values for either men (0.84 ± 0.16 IU/ml of plasma) or nonpregnant women (0.91 ± 0.16 IU/ml of plasma). These differences were clearly reflected in the values of releasable tissue plasminogen activator that we calculated. Levels for pregnant women demonstrated a mean of only 0.06 ± 0.02 IU/ml of plasma compared with values of 0.60 ± 0.14 IU/ml of plasma in men ($p < 0.01$) or 0.74 ± 0.15 IU/ml of plasma in nonpregnant women ($p < 0.01$). These data reflect a tenfold to twelvefold decline in levels of releasable tissue plasminogen activator during pregnancy.

Since comparison of data for men and nonpregnant women demonstrated no significant differences for preocclusion or postocclusion levels of releasable tissue plasminogen activator, the two groups were combined and data compared for the entire group versus pregnant subjects (Table II). Since men tended to demonstrate slightly lower levels of releasable tissue plasminogen activator, this comparison would tend to weigh the interpretation against the difference hypothesis. However, the same results were obtained with an average releasable tissue plasminogen activator about elevenfold lower during pregnancy.

The data in Tables I and II may be interpreted as normal levels of plasminogen activators in a group of healthy subjects assayed by use of the most specific assays currently available and with fibrin monomer to stimulate tissue plasminogen activator. It is the largest group of normal individuals yet reported, with only a handful of subjects previously described by this type of assay.

The data from the pregnant subjects also were stratified by trimester of pregnancy (Table III). The acti-

*Comparisons of prepartum and postpartum values with respect to preocclusion, postocclusion, and releasable tissue plasminogen activator were all statistically significant ($p < 0.01$) by paired *t* test.

vator levels measured in the preocclusion and postocclusion samples as well as the calculated releasable tissue plasminogen activator demonstrated no significant differences. It is concluded that the changes in vascular stores of tissue plasminogen activator decline rapidly in pregnancy (at least from week 10) and then remain at low levels.

Plasminogen activators in the postpartum period. During the course of this study seven women reached term and were delivered of their neonates, offering an opportunity for assessment of tissue plasminogen activator in the immediate postpartum period. In these subjects blood was drawn 2 days after delivery. Although the numbers are small a dramatic change occurred after delivery (Table IV). Values for both preocclusion and postocclusion samples were increased after delivery, and releasable tissue plasminogen activator returned to near-normal levels by this time ($p < 0.01$).

Fast-acting tissue plasminogen activator inhibitor. Measurements of the fast-acting tissue plasminogen activator inhibitor present in plasma were obtained on the preocclusion plasma samples for the entire study group. These data indicate that men and nonpregnant women have essentially the same levels of circulating inhibitor (Table I). When the entire study group of pregnant women was considered, levels of inhibitor were not significantly altered, 8.99 ± 0.17 IU/ml of plasma versus 8.63 ± 0.22 IU/ml of plasma for men and 8.46 ± 0.19 IU/ml of plasma for nonpregnant women. However, when the data were stratified by trimester it became evident that levels of inhibitor rise with each trimester (Table III), with the largest difference occurring between the second and third trimesters. Comparison of either the first or second trimester versus the third trimester yielded a statistically significant difference ($p < 0.05$). Overall, inhibitor activity rose from 8.40 ± 0.27 IU/ml of plasma in the first trimester to 9.92 ± 0.09 IU/ml of plasma in the third trimester.

Levels of tissue plasminogen activator inhibitor were also measured in the seven available subjects after delivery (Table IV). Overall, for these women inhibitor levels fell from 9.25 ± 0.11 IU/ml of plasma in the third trimester of pregnancy to 8.54 ± 0.21 IU/ml of

plasma immediately after delivery. A trend is clearly evident in these data but does not reach the level of statistical significance ($p = 0.10$).

Comment

Previous studies have indicated alterations in both procoagulants and fibrinolytic activity during pregnancy.[1, 2] Most procoagulants increase in concentration during pregnancy,[1, 2] but the effect on fibrinolysis appears selective. Plasminogen levels increase significantly during pregnancy, peaking at week 28 of pregnancy.[1, 2] Levels remain elevated through about the first 8 weeks after delivery.[1, 2] By contrast, total fibrinolytic activity decreases as assessed by integrative assays of fibrinolysis, namely, the euglobulin lysis time[1, 2] or the fibrin plate method.[14] These data suggested that plasminogen activator levels might decrease in pregnancy; however, they are indirect measurements, and determination of activator is at best only semiquantitative. More recently, it has been suggested that tissue plasminogen activator inhibitor levels increase throughout pregnancy, particularly in the last trimester.[10] However, in this study only 2 IU tissue plasminogen activator per milliliter was added to titrate the inhibitor, and a number of normal subjects may exceed such levels, resulting in a spurious value for the inhibitor. In a subsequent study we found that this amount of tissue plasminogen activator was insufficient to titrate all the inhibitor.[7]

In the present study we have applied readily quantifiable assays of tissue plasminogen activator and its specific inhibitor to plasma from pregnant women and have compared the observed levels with those found in men and nonpregnant women. The inhibitor assay used a large excess of tissue plasminogen activator, 10 IU/ml, to titrate the inhibitor so that it is unlikely that inhibitor levels were underestimated. To date, this group ($n = 118$) is the largest cohort of normal subjects surveyed for tissue plasminogen activator and its newly described fast-acting inhibitor. These assays make it possible to dissect the nature of the fibrinolytic defect of pregnancy.

Our data indicate that a profound suppression in release of vascular tissue plasminogen activator occurs throughout the course of pregnancy. The limited data available after delivery suggest that there is a rapid return to normal levels of releasable activator. Basal levels of activator may actually be elevated immediately after delivery. These changes may be mediated by a number of pregnancy-associated changes in hormonal regulation. The elevation in plasma estrogen levels seen in pregnancy may suppress vascular stores of tissue plasminogen activator, although most data suggesting such a correlation relate to synthetic rather than natural estrogens.[15] The fall in estrogens around parturition may result in a rapid rebound in releasable tissue plasminogen activator. Rising levels of plasma oxytocin may also contribute to high basal levels of plasminogen activators because homologous peptides such as vasopressin and its analogues will trigger tissue plasminogen activator release.[16] Similarly, increases in plasma epinephrine concentration, likely to occur with the stress of delivery, also trigger release of vascular activator stores.[16]

The rise in plasma inhibitor levels may correlate with changes in the placenta itself. This tissue is a rich source of fibrinolytic inhibitors,[1, 2] and during the course of its maturation it may secrete increasing levels of inhibitors such as we observed in the third trimester. In this regard it is interesting to consider a possible role for defective production of placental inhibitor in the etiology of abruptio placentae or premature placental separation. In this setting there would be available circulating tissue plasminogen activator in the presence of high circulating plasminogen levels that might make the patient more prone to bleeding. Such bleeding in the retroplacental area may contribute to placental separation.

The rise in tissue plasminogen activator inhibitor levels observed in the present report is not as great as in the one previous study of this factor.[10] This difference may reflect variations in the assay conditions as this earlier study may not have used an adequate concentration of tissue plasminogen activator to quench all of the inhibitor present. It is apparent from the values reported[10] that a concentration of tissue plasminogen activator higher than the 2 IU/ml initially specified must have been added to some of the samples since values for inhibitor sometimes exceeded 2 IU/ml plasma. The kinetics of a bimolecular reaction require that one component be kept constant; otherwise the values may not be comparable. The present study suggests that the rise in tissue plasminogen activator inhibitor is not sufficient to account for the profound suppression in tissue plasminogen activator levels that was observed. This is particularly pertinent as this suppression was observed throughout pregnancy, whereas the inhibitor rise was seen only in the third trimester. Our data also suggest that tissue plasminogen activator inhibitor returns to nonpregnant levels relatively rapidly, although the data do not reach statistical significance at 2 days after delivery ($p = 0.10$). A major problem in this regard is the timing of the blood drawing during the third trimester. It is quite possible that levels would be higher than those we report if sampling were performed just before delivery. It would be very difficult to control for this variable since an extensive effort would be required to obtain multiple samples in the last trimester. It is apparent, however, that return to basal levels must occur over days rather than weeks.

Taken with previous studies, the present observations

suggest that a true hypercoagulable state exists in pregnancy. The immediate postpartum period presents the possibility of a rebound phenomenon since it is a time when high levels of plasminogen[4] may not be counterbalanced by low activator levels and high levels of inhibitor. It is conceivable that such alterations could at times contribute to postpartum bleeding in marked contrast to the prepartum thromboembolic tendency. These observations do not rule out the possibility that some women may remain in a hypercoagulable state for some weeks after delivery since a number of the procoagulant proteins such as fibrinogen and factor X remain elevated after delivery.[4] In many subjects as many as 8 weeks are required before the coagulation system returns to a normal balance. These hypotheses appear consistent with the paradox observed in some women in the early postpartum period who suffer a thromboembolic event while also manifesting a bleeding diathesis.

We thank Connie E. Hughes, R.N., for collecting blood samples from the subjects reported in this study.

The effects of human chorionic gonadotropin on growth and steroidogenesis of the human fetal adrenal gland in vitro

Maysan Abu-Hakima, B.Sc., Charlotte L. Branchaud, Ph.D., Cynthia G. Goodyer, Ph.D., and Beverley E. Pearson Murphy, M.D., Ph.D.*

Montreal, Quebec, Canada

This study examined the effects of human chorionic gonadotropin, adrenocorticotropin, human luteinizing hormone, and mouse epidermal growth factor on growth (thymidine incorporation) and steroidogenesis (dehydroepiandrosterone sulfate production) of human fetal zone adrenal cells in monolayer culture. Two preparations of human chorionic gonadotropin extracted from pregnancy urine were used, one highly purified (National Institutes of Health, CR-121) and one less pure (Sigma). Thymidine incorporation was increased twofold to tenfold in cultures exposed to the Sigma human chorionic gonadotropin preparation or to mouse epidermal growth factor as compared to control. Pure National Institutes of Health human chorionic gonadotropin and luteinizing hormone had no effect on growth. When adrenocorticotropin was added alone or in combination with Sigma human chorionic gonadotropin or mouse epidermal growth factor, growth was decreased. Dehydroepiandrosterone sulfate production was stimulated by adrenocorticotropin but not by human luteinizing hormone, human chorionic gonadotropin, or mouse epidermal growth factor. These results suggest that human pregnancy urine contains a growth factor which remains to be identified but that pure human chorionic gonadotropin has no mitogenic or steroidogenic effects on the cultured fetal zone cells of the human fetal adrenal gland. (Am J Obstet Gynecol 1987;156:681-7.)

Key words: Fetal adrenal, growth, steroidogenesis, human chorionic gonadotropin, adrenocorticotropin

The unique pattern of growth and development as well as the steroidogenic capacity of the human fetal adrenal is well recognized,[1] but little is known about what regulates these activities in the definitive and fetal zones. Although a functional pituitary is important for maintenance of the fetal adrenal in the later stages of pregnancy, the normal appearance of the gland up to about 16 weeks in anencephalic fetuses[2] and the rapid involution of the fetal zone after birth[3] has suggested that extrapituitary factors may be involved in its development during early gestation.

Adrenocorticotropin (ACTH) is the principal pituitary factor controlling fetal adrenocortical function. There is also evidence that other peptides may be involved, including the placental hormone, human chorionic gonadotropin (hCG).[4-6] However, reports of the effects of hCG on growth and steroidogenesis in the fetal adrenal have been conflicting.[4-7]

In the present study, fetal zone cells of adrenal glands from midgestation human fetuses were maintained in monolayer culture. Growth and steroidogenic activity of these cells were examined during chronic exposure to a pure and an impure preparation of hCG, ACTH, human luteinizing hormone, or mouse epidermal growth factor. Growth was assessed by measuring the incorporation of tritiated thymidine into deoxyribonucleic acid, and steroidogenesis was characterized by dehydroepiandrosterone sulfate production.

Material and methods

Materials. ACTH$^{1-39}$ (pACTH) (Duracton, a long-acting preparation of porcine ACTH containing carboxymethylcellulose; 1 mU is approximately equivalent to 10 ng of synthetic human ACTH) was purchased from Nordic Biochemical Laboratories (Montreal, Quebec). Mouse epidermal growth factor was obtained from Collaborative Research (Lexington, Massachusetts) and purified hCG (CR-121) and human luteinizing hormone (LER-960) from the National Hormone and Pituitary Program of the National Institute of Arthritis,

From the Reproductive Physiology Unit, Montreal General Hospital, the Endocrine Research Laboratory, Montreal Children's Hospital, and the Centre for the Study of Reproduction, McGill University.

Diabetes, and Digestive and Kidney Diseases, National Institutes of Health (NIH), Bethesda, Maryland. The less pure hCG was obtained from Sigma Chemical Co. (St. Louis, Missouri); this is a crude preparation from human pregnancy urine involving minimal purification and displays a number of bands on electrophoresis (Sigma, personal communication). Ham's F-10 powdered culture medium and heat-inactivated fetal bovine serum were purchased from Grand Island Biological Company (Burlington, Ontario), amphotericin B (Fungizone) from Squibb Canada, Inc. (Montreal, Quebec), penicillin G (Crystapen) from Glaxco Laboratories (Montreal, Quebec), and gentamicin (Garamycin) from Schering (Pointe Claire, Quebec). Collagenase (type IA) and deoxyribonuclease were obtained from Sigma Chemical Co. (St. Louis, Missouri) and multiwell culture plates from Falcon Plastics (Los Angeles, California). Tritiated thymidine and dehydroepiandrosterone sulfate were purchased from New England Nuclear Canada Ltd. (Lachine, Quebec), and antiserum to dehydroepiandrosterone sulfate was obtained from Endocrine Sciences (Tarzana, California).

Preparation of monolayer cultures. Human fetal adrenal glands were obtained at the time of therapeutic abortion by dilatation and curettage (Department of Obstetrics and Gynecology, Hopital Notre-Dame, with approval from the local institutional ethics committees). Fetal age (gestational age less 2 weeks) was determined according to foot length.[8] The glands were placed in sterile vials containing cold Ham's F-10 medium and antibiotics and transported on ice to the laboratory.

After removal by dissection of any surrounding connective tissue, the capsule including the definitive zone was carefully removed from each gland. The remaining fetal zone was minced in dispersion medium consisting of 1 mg/ml collagenase and 0.1 mg/ml deoxyribonuclease in Ham's F-10 containing 10% fetal bovine serum and antibiotics. The cells were harvested every 20 minutes, spun down, and the pellet resuspended in culture medium (Ham's F-10 supplemented with 10% fetal bovine serum and antibiotics: 5 μg/ml of amphotericin B, 200 IU/ml of penicillin G, and 40 μg/ml of gentamicin). After two rinses the cells were distributed in multiwell (1.9 cm^2) plates in a volume of 0.5 ml (6 to 9 × 10^4 cells) per well. The plates were then incubated at 37° C in a humidified atmosphere with 5% carbon dioxide in air.

After 24 hours an additional 0.5 ml of culture medium was added. After 48 hours the plating medium was discarded and replaced with fresh medium. For the duration of each experiment the spent media were collected daily and replaced with 1 ml of fresh medium. Test substances were added directly to the culture wells in 20 μl of normal saline solution. Three experiments were performed, each with use of adrenals from two fetuses. The ages of the fetuses in experiment 1 were 14 and 15 weeks, in experiment 2 they were 13 and 15 weeks, and in experiment 3 they were 11 and 11.5 weeks. Experimental design was dictated by the amount of tissue available at any one time.

Tritiated thymidine incorporation. Growth of the fetal adrenal cells in culture was assessed by thymidine incorporation into deoxyribonucleic acid. During a period of active proliferation, before the cultures had reached confluence, each well received 1.0 ml of culture medium containing the appropriate test substance and 1 μCi of methyl–tritiated thymidine. The media were collected after 24 hours, and each well was rinsed three times with saline solution. To detach the cells, 0.5 ml of 0.6N sodium hydroxide was added to each well and the plates were incubated for a further 8 hours, after which the medium and detached cells were collected. To lyse the cells and precipitate the deoxyribonucleic acid, 0.5 ml of an ice-cold solution of 60% trichloroacetic acid was added to the cell suspension, giving a final concentration of 30% trichloroacetic acid. The trichloroacetic acid precipitates were stored at 4° C until assayed, when they were collected by rapid filtration with use of a Millipore 30254 sampling manifold (Millipore Corp., Bedford, Massachusetts). After the initial filtration, any unbound radioisotope was removed by washing the filters four times with ice cold 10% trichloroacetic acid. The filters were dried overnight at 37° C, placed in counting vials, and 4 ml of phosphotoluene scintillation fluid (4 gm of 2,5-diphenyloxazole (PPO) and 0.1 gm of 1,4-bis(5-phenyl-2-oxazolyl)-benzene (POPOP) per liter of distilled toluene) were added. The radioactivity was measured in an LKB Rackbeta II liquid scintillation counter. Final results were expressed as total counts per minute of tritiated thymidine taken up by the cells in each well.

Steroid production. Dehydroepiandrosterone sulfate and cortisol were measured by radioimmunoassay as described previously.[9] Because cortisol production by these cultures was very low or undetectable, the cortisol data are not presented.

Statistical analysis. Data from the thymidine incorporation and dehydroepiandrosterone sulfate studies were analyzed with analysis of variance followed by Duncan's multiple range test.

Results

Adrenal cell cultures. Freshly dispersed fetal zone cells from human fetal adrenal glands were successfully maintained in monolayer culture for up to 10 days. The cells attached within 48 hours of plating and retained their ability to secrete dehydroepiandrosterone sulfate. Mitotic activity was observed in the cultures throughout the incubation period. Epithelial cells were the predominant type found; very few fibroblasts were

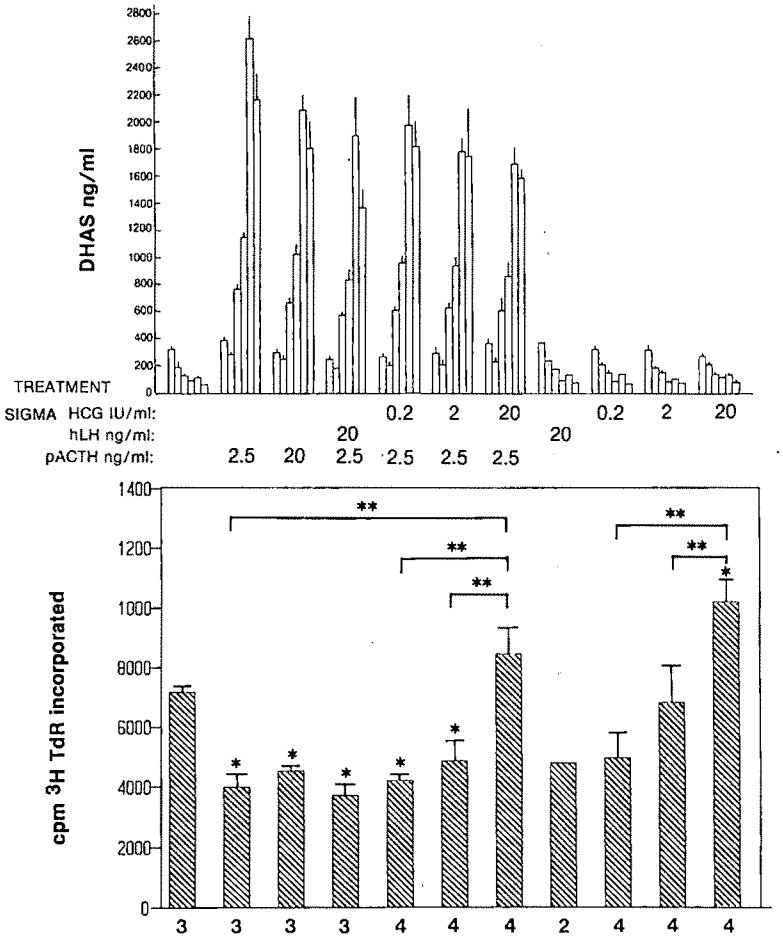

Fig. 1. *Upper panel:* The production of dehydroepiandrosterone sulfate on days 5 to 10 in culture by fetal zone cells from pooled adrenals of a 14- and a 15-week-old fetus. Each *bar* within a treatment group denotes the level of dehydroepiandrosterone sulfate per milliliter (mean ± SEM) produced during a 24-hour period. The first *bar*, representing day 5 of the experiment, shows the basal level. Test substances were added to the cultures daily from day 6 onward. *Lower panel:* The corresponding thymidine incorporation study for each treatment group (mean ± SEM), determined on day 11. *Numerical values* under the *bars* refer to the number of wells in each treatment group. Differences that were significantly different from control or between groups are indicated as *$p < 0.05$ and **$p < 0.01$.

seen. Large islands of what appeared to be adrenal medullary cells with extensive dendritelike connections were also present.

Tritiated thymidine incorporation. In experiment 1 (Fig. 1), both 2.5 and 20 ng/ml of pACTH inhibited ($p < 0.05$) tritiated thymidine uptake by the cultures. In the absence of pACTH, Sigma hCG significantly stimulated ($p < 0.05$) tritiated thymidine incorporation at 20 IU/ml but not at 0.2 or 2 IU/ml. In the presence of pACTH and the two lower doses of Sigma hCG, tritiated thymidine incorporation was similar to that observed in the presence of pACTH alone. The highest dose of Sigma hCG was able to block the inhibitory effects of pACTH. Human luteinizing hormone appeared to have an inhibitory effect at 20 ng/ml, but in the presence of 2.5 ng/ml of pACTH, thymidine uptake did not differ from that with pACTH alone.

In experiment 2 (Fig. 2), pure NIH hCG had no significant effect even at a dose of 1000 ng/ml. Mouse epidermal growth factor, however, at a dose of 10 ng/ml increased tritiated thymidine uptake more than threefold ($p < 0.01$). In the presence of pACTH at 2.5 ng/ml, mouse epidermal growth factor stimulation was reduced to a twofold increase but was still significant when compared to controls ($p < 0.05$).

In experiment 3 (Fig. 3), Sigma hCG (20 ng/ml) significantly increased tritiated thymidine incorporation over controls and was able to block the inhibitory effects of 2.5 ng/ml pACTH. Again pure NIH hCG had no significant effects at either dose level of 100 or 1000 ng/ml.

Dehydroepiandrosterone sulfate production. In experiment 1, production of dehydroepiandrosterone sulfate was determined from days 5 to 10 (Fig. 1). Con-

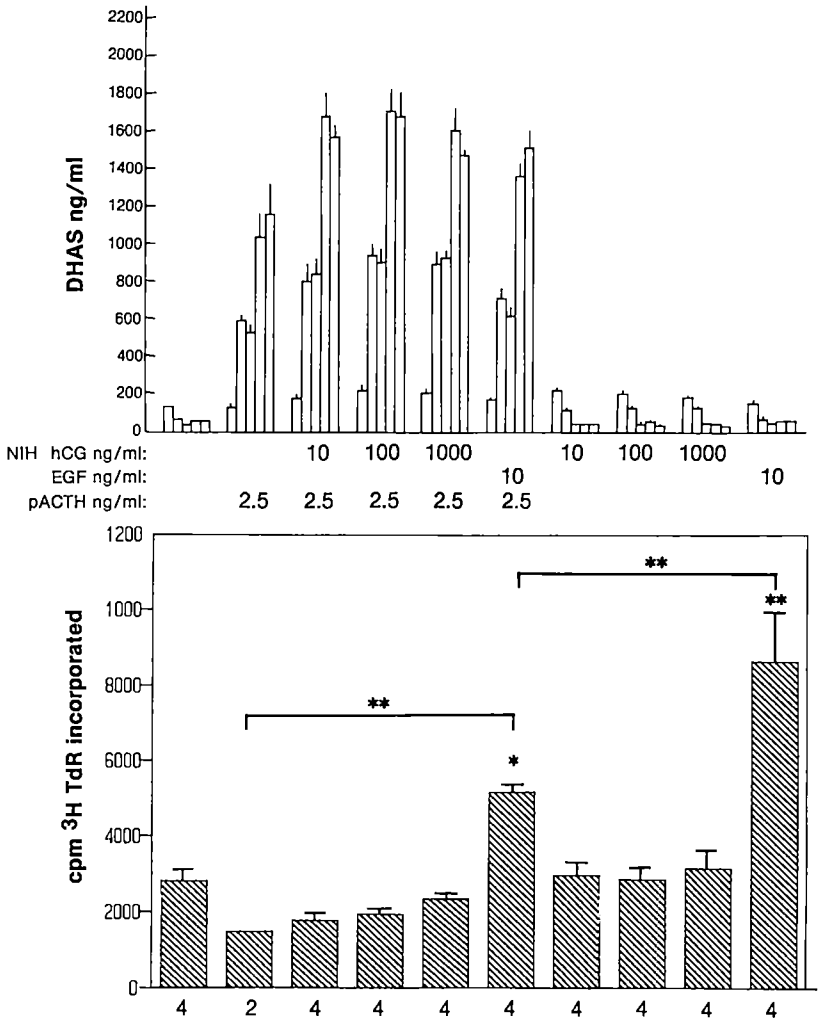

Fig. 2. Fetal adrenal cells were pooled from a 13- and a 15-week-old fetus. The experimental design was similar to that in Fig. 1, except that the *upper panel* shows the production of dehydroepiandrosterone sulfate on days 3 to 7 in culture. The first *bar*, representing day 3 of the experiment, shows the basal level of dehydroepiandrosterone sulfate production. Test substances were added daily from day 3 onward and thymidine incorporation *(lower panel)* was determined on day 8.

centrations of dehydroepiandrosterone sulfate on day 5 ranged from 250 to 399 ng/ml. On day 6 the levels were lower, with mean concentrations between 188 and 287 ng/ml. In the absence of any test substances, the levels of dehydroepiandrosterone sulfate in the control group continued to decline throughout the culture period, reaching a mean concentration of 66 ng/ml on day 10.

Beginning on day 6, various test substances were added to the culture medium. There was a marked increase in dehydroepiandrosterone sulfate when pACTH was added: the levels of dehydroepiandrosterone sulfate doubled in the first 24 hours after the addition of both the low (2.5 ng/ml) and high (20 ng/ml) doses of pACTH and continued to increase to peak levels (2000 ng/ml) on day 9 ($p < 0.01$ on day 10). No effects of luteinizing hormone or Sigma hCG were seen.

In experiment 2 the fetal zone cells were cultured for 7 days. The levels of dehydroepiandrosterone sulfate measured from days 3 to 7 are shown in Fig. 2. On day 3 the levels of dehydroepiandrosterone sulfate ranged from 130 to 208 ng/ml. In the control group the levels decreased to 38 ng/ml by day 5 and remained at this level until the end of the culture period.

Various test substances were added from day 3. In the 24 hours following the addition of pACTH (2.5 ng/ml), the concentration of dehydroepiandrosterone sulfate tripled. The levels of dehydroepiandrosterone sulfate increased steadily throughout the incubation period, reaching a maximum concentration of 1200 ng/ml on day 7 ($p < 0.01$).

Production of dehydroepiandrosterone sulfate by the fetal zone cells exposed to pure NIH hCG plus pACTH was comparable to that by cells treated with

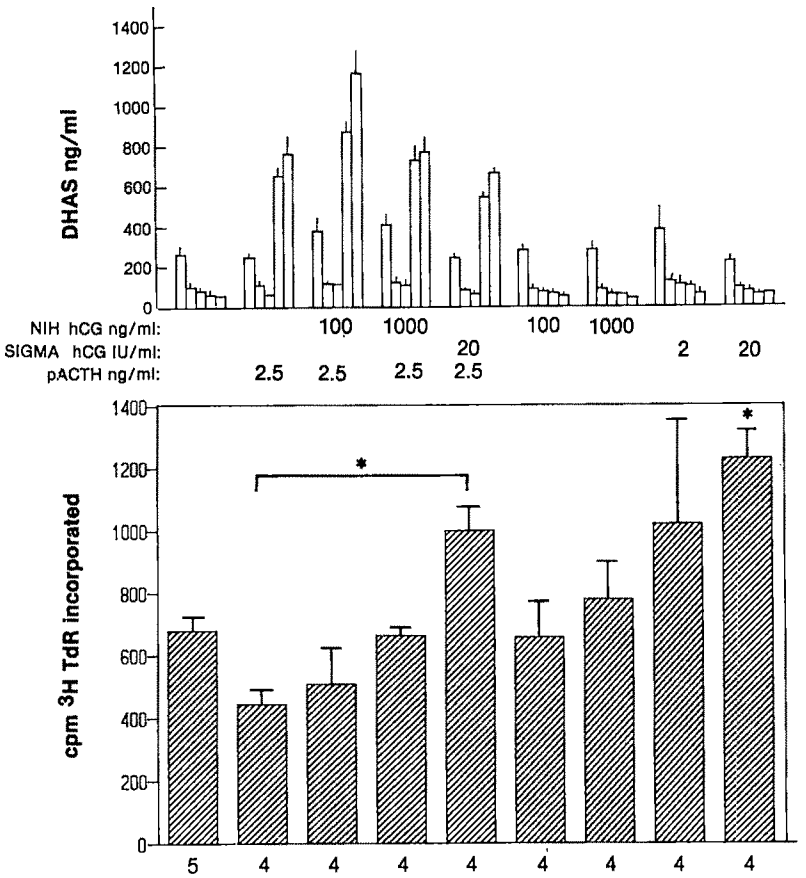

Fig. 3. Fetal adrenal cells were pooled from an 11- and an 11.5-week-old fetus. The experimental design was similar to that in Fig. 1, except that the *upper panel* shows the production of dehydroepiandrosterone sulfate on days 3 to 7. The first *bar*, representing day 3 of the experiment, shows the basal level of dehydroepiandrosterone sulfate production. Test substances were added daily from day 5 onward, and thymidine incorporation *(lower panel)* was determined on day 8.

pACTH alone. The pattern of dehydroepiandrosterone sulfate production by fetal zone cells exposed to mouse epidermal growth factor plus a low dose of ACTH (2.5 ng/ml) was also comparable to that by cells exposed to ACTH alone. When pure NIH hCG or mouse epidermal growth factor was added to fetal zone cells in the absence of ACTH, the levels of dehydroepiandrosterone sulfate from days 4 to 7 were similar to the pattern observed in the control group.

In experiment 3, fetal zone cells were maintained in culture for 7 days. As shown in Fig. 3, the dehydroepiandrosterone sulfate levels on day 3 ranged from 230 to 410 ng/ml in all the wells. In the control group, levels of dehydroepiandrosterone sulfate were reduced on day 4 and continued to decrease, reaching a plateau on day 5.

Test substances were added from day 5. Compared to the control group, there was an increase ($p < 0.01$) in dehydroepiandrosterone sulfate levels when the cells were exposed to pACTH (2.5 ng/ml) either alone or in combination with pure NIH hCG (0.1 or 1 μg/ml) or a high dose (20 IU/ml) of Sigma hCG. The pattern of dehydroepiandrosterone sulfate production in the presence of either NIH or Sigma hCG alone was similar to that observed in the control groups, in which basal levels of dehydroepiandrosterone sulfate were maintained.

Comment

The size of the fetal adrenal relative to body weight is enormously increased during gestation, reaching a peak around 15 weeks. at which time it equals the size of the fetal kidney; it remains large with another small increase in relative weight just before parturition.[1] The absolute weight increases steadily to a maximum just before delivery.[1] During the first month of postnatal life the fetal adrenal decreases in size by about half and thereafter grows proportionately less than other tissues.

Numerous studies in the child and adult have shown that ACTH administration in vivo results in increased adrenal weight as well as steroidogenic activity.[1] Similar

studies in the human fetus are obviously limited. Johannisson[4] has observed morphologic changes indicative of increased steroidogenic activity in both zones of the fetal adrenal of normal fetuses treated with ACTH in utero before termination of pregnancy at midgestation. Lanman[10] and Honnebier et al.[11] have reported an increase in both size and functional activity of the fetal zone in anencephalic newborn infants after ACTH treatment. However, in these anencephalic infants the fetal adrenal cortex appears to develop normally until about 16 weeks of gestation, even when serum ACTH levels are low or undetectable.[2] In addition, although there is a steady decrease in serum ACTH levels from midgestation to postnatal life during normal gestation,[12] it is only after birth that there is rapid involution of the fetal zone accompanied by the concomitant development of the adult zone. These observations have prompted the proposal that factors other than ACTH are involved in regulating growth of the fetal zone of the fetal adrenal. Indeed such factors have long been sought but remain to be identified.

Because it has not been feasible to study human fetal adrenal glands in vivo, extensive use has been made of in vitro methodologies[7, 12-14] to examine both steroidogenic activity and growth of the fetal adrenal cells. Using monolayers, Crickard et al.[15] have proposed that the growth-promoting effect of ACTH in vivo may be mediated by specific growth factors. They demonstrated that both mouse epidermal growth factor and bovine fibroblast growth factor were potent mitogens for human fetal adrenal cells. In the present study, mouse epidermal growth factor resulted in a threefold increase in the incorporation of thymidine into fetal zone cells from the midgestation gland, while it had no effect on dehydroepiandrosterone sulfate production. However, the observation that ACTH had a significant inhibitory effect on epidermal growth factor–stimulated proliferation of the cells suggests that the effects of ACTH and epidermal growth factor on growth may be antagonistic.

In view of the rapid postnatal involution of the fetal adrenal cortex, the fetoplacental unit is a likely source of adrenocorticotropic factors. It has been suggested that placental hCG may be one of these factors, although previous studies have produced conflicting data.[4-7] From the present findings it is clear that pure NIH hCG does not stimulate proliferation or steroidogenesis of the human fetal adrenal although this preparation demonstrated biologic activity in the rat ventral prostate weight gain assay. On the other hand, the less pure Sigma hCG preparation markedly stimulates thymidine incorporation with no effect on dehydroepiandrosterone sulfate production.

Since the Sigma hCG is prepared from pooled pregnancy urine, we postulate that the trophic effect of hCG we and others have observed may be mediated by a contaminating growth factor. Although the nature of this factor is not yet known, it is quite possibly placental in origin. This would be consistent with the concept of an involvement of extrapituitary factors in the regulation of adrenal development during gestation.

Since dehydroepiandrosterone sulfate is considered to be the principal steroid produced by the fetal zone in vitro,[6, 9, 13, 16] the detection of dehydroepiandrosterone sulfate in incubation media from the monolayer cultures was used as an index of steroidogenic activity. The only significant increase in dehydroepiandrosterone sulfate levels occurred in response to ACTH. Despite quantitative variability in this response, the pattern of endogenously released dehydroepiandrosterone sulfate was similar in all three experiments and is in agreement with the observations of others.[13, 14, 16] The decline in dehydroepiandrosterone sulfate levels observed with time in the absence of ACTH provides further support for the lack of steroidogenic factors in fetal bovine serum. The present results support the concept that ACTH is the principal factor regulating androgen production by the fetal adrenal cortex. In addition, it is apparent that separate mechanisms control growth and steroidogenesis in the midterm gland.

We gratefully acknowledge the cooperation of Dr. Yves Lefebvre (Department of Obstetrics and Gynecology, Hopital Notre Dame) in obtaining fetal tissues.

Reliable criteria for the prenatal sonographic diagnosis of alobar holoprosencephaly

Michael F. Greene, M.D., Beryl R. Benacerraf, M.D., and Fredric D. Frigoletto, Jr., M.D.
Boston, Massachusetts

A series of 10 consecutive cases of alobar holoprosencephaly is described. The disorder was diagnosed prenatally by ultrasound according to two criteria: (1) a large central fluid collection in the fetal head, with no visible midline structures but with the presence of a mantle around the fluid collection and fusion of the thalami and corpus striatum, and (2) sonographic abnormalities of the face, including hypotelorism, central clefts, facial asymmetry, and abnormal orbits. (AM J OBSTET GYNECOL 1987;156:687-9.)

Key words: Ultrasound, prenatal diagnosis, alobar holoprosencephaly

Alobar holoprosencephaly is a severe intracranial abnormality characterized by failure of proper cleavage of the prosencephalon, most often accompanied by incomplete midfacial development. The prenatal sonographic diagnosis of holoprosencephaly has been described[1, 2]; however it has been suggested that sufficient diagnostic accuracy has not yet been established so that appropriate obstetric management can be effected.[1]

We report here a series of 10 consecutive cases of alobar holoprosencephaly diagnosed prenatally with the use of two criteria. The intracranial criterion was a large central fluid collection in the fetal head, with no visible midline structures but with the presence of a mantle around the fluid collection and fusion of the thalami and corpus striatum (Fig. 1). The second criterion was sonographic abnormalities of the face, which included hypotelorism, central clefts, facial asymmetry, and abnormal orbits (Fig. 2). Ten consecutive cases, ranging from 16 to 38 weeks' gestation, satisfied both the intracranial and facial criteria for the diagnosis of alobar holoprosencephaly. The final diagnosis in all 10 cases was confirmed after either elective abortion or delivery (Table I). Karyotyping was done in nine of 10 cases, revealing four instances of trisomy 13 and one of triploidy. Three fetuses were aborted, one died in utero, and the other six died within 2 months of life. In the two additional cases where the presumptive diagnosis of holoprosencephaly was suggested on the basis of intracranial criteria but where no facial abnormality could be seen sonographically, after birth the infants were found to have severe hydrocephalus.

Alobar holoprosencephaly is a severe intracranial abnormality with a very poor prognosis. Affected infants usually die shortly after birth, although some can survive for 6 months and are profoundly retarded or have amentia.[3]

It is therefore crucial for the parents that this diag-

Fig. 2. Oblique longitudinal view of the fetal face showing a large central cleft (Case No. 10).

Table I. Findings in 10 cases

Case No.	*Gestational age at diagnosis (wk)*	*Ultrasound findings*	*Karyotype*	*Outcome*
1	26-28	Facial cleft and large central ventricle	Normal	Term delivery, neonatal death, findings confirmed at autopsy
2	16	Large central ventricle, cyclopia	Trisomy 13	Elective abortion, findings confirmed at autopsy
3	21	Twins, one normal, one with cyclopia, central ventricle, microcephaly	Normal	Normal twin survived, abnormal twin died at birth, findings confirmed at autopsy
4	26-27	Huge head, huge ventricle, fused thalami, abnormally small eyes, polyhydramnios	Normal	Term intrauterine death, findings confirmed at autopsy
5	32	Large central ventricle, cyclopia, oligohydramnios	Triploidy	Neonatal death, findings confirmed at autopsy
6	21	Large central ventricle, cyclopia	Trisomy 13	Elective abortion, findings confirmed at autopsy
7	30	Large central ventricle, asymmetry of orbits (small)	Normal	Findings confirmed at autopsy
8	19	Huge central ventricle, large midline cleft	Trisomy 13	Elective abortion, findings confirmed at autopsy
9	36	Microcephaly, central ventricle, abnormally small eyes and hypotelorism	Not done	Findings confirmed clinically at birth and radiographically, died at 2 mo, no autopsy done
10	38	Microcephaly, central ventricle, huge facial cleft and hypotelorism	Trisomy 13	Term delivery, neonatal death at 1 mo, findings confirmed at autopsy

nosis be made reliably in utero with a very high degree of accuracy so that alternatives of obstetric management can be offered. Our observations indicate that hydrocephalus and hydranencephaly can be severe enough to be confused with holoprosencephaly. We believe therefore that a careful examination of the face is necessary to provide the additional information required to diagnose reliably alobar holoprosencephaly in utero.

Occasionally a fetus with alobar holoprosencephaly can have normal or near normal facies.[1] It follows therefore that our criteria may not identify every fetus with holoprosencephaly. Also some fetuses can have severe midline facial abnormalities without the intracranial findings. If, however, a fetus fulfills both the intracranial and facial criteria described here for alobar holoprosencephaly, our data indicate that the diagnosis is sufficiently reliable that it can be used to offer the patient various obstetric options. Because the number of cases of holoprosencephaly presenting to a given laboratory is limited, confirmation of our findings in large numbers of patients will require further study.

Fetal cardiac tumor: A prenatal echocardiographic marker for tuberous sclerosis

C. D. Gresser, R.N., R.D.M.S., J. Shime, M.D., H. Rakowski, M.D., J. F. Smallhorn, M.B., B.S., A. Hui, M.D., and J. J. Berg, M.B., M.Sc.

Toronto, Ontario, Canada

Auscultation of a fetal bradyarrhythmia led to the prenatal echocardiographic detection of an intracardiac tumor. After birth the diagnosis of tuberous sclerosis was established. Therapeutic implications for current and future pregnancies, when a fetal cardiac tumor is found, are discussed. (Am J Obstet Gynecol 1987;156:689-90.)

Key words: Fetal heart tumors, echocardiography, tuberous sclerosis

Cardiac neoplasms in the fetus may result in stillbirth or early neonatal death. As with infants and young children, these rare tumors are almost exclusively rhabdomyomas, although a case of right atrial hemangioma has been described at 28 weeks' gestation. In recent years, echocardiography has permitted identification of structural anomalies of the fetal heart including, to the best of our knowledge, five cases of cardiac tumor. We present an additional case in which the echocardiographic diagnosis was preceded by detection of a fetal bradyarrhythmia.

From the Divisions of Maternal-Fetal Medicine and Cardiology, Toronto General Hospital, and the Divisions of Cardiology and Genetics, Hospital for Sick Children, and the University of Toronto School of Medicine.
Supported by the Ontario Heart Foundation.

Case report

A healthy 31-year-old primigravid woman experienced an uneventful pregnancy until 32 weeks' gestation, when the fetal heart rate was noted to be slow and irregular. M-mode examination revealed an irregular bradycardia of approximately 100 bpm. Atrioventricular dissociation was sought but was not demonstrable. No structural anomaly was observed until the third examination at 34 weeks' gestation disclosed an echogenic 0.9 cm mass on the posterior aspect of the right atrium near the point of entry of the superior vena cava (Fig. 1). Another prominent echo was present at the base of a left ventricular papillary muscle. At 38 weeks, the bradycardia became more profound (baseline approximately 60 bpm), and ventricular function appeared to be reduced. Induction of labor was undertaken but progress was inadequate and cesarean delivery of a 3001 gm female infant was performed. Apgar scores were 8 and 9 at 1 and 5 minutes, respectively. Neonatal echo examination confirmed the right atrial

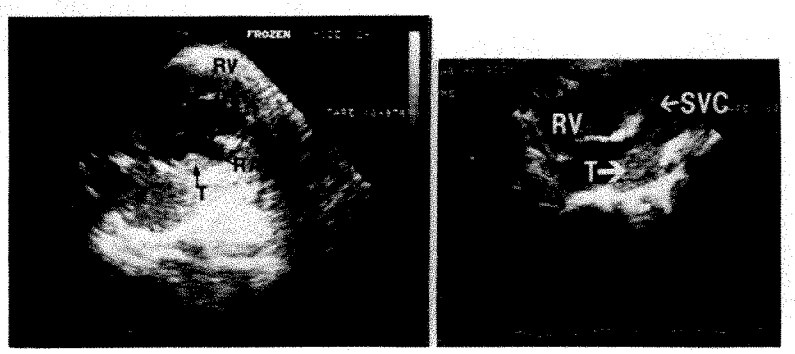

Fig. 1. Right atrial tumor noted in the fetal heart at 35 weeks' gestation. *Left:* Four-chamber view. *T,* Tumor mass; *RA,* right atrium; *RV,* right ventricle. *Right:* The tumor mass *(T)* is seen at the junction of the superior vena cava *(SVC)* and right atrium. *RV,* Right ventricle.

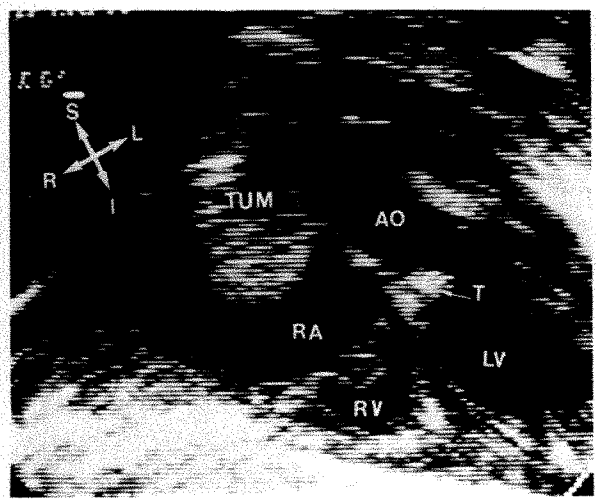

Fig. 2. Neonatal echo revealing right atrial tumor mass *(TUM)* and a smaller interventricular septal tumor *(T).*

tumor as well as smaller lesions in the left ventricle near the apex, at the base of the papillary muscle, and on the interventricular septum (Fig. 2). An electrocardiogram revealed a variable P-wave morphology consistent with a wandering atrial pacemaker. At 5 months of age, hypopigmented skin patches developed, leading to a diagnosis of tuberous sclerosis. The infant remained hemodynamically stable, and by 1 year of age, the right atrial mass appeared relatively smaller and the arrhythmia was less pronounced, with longer runs of sinus rhythm. Developmental, neurological, and renal assessments have remained normal. Family studies failed to reveal any evidence of tuberous sclerosis, thus raising the possibility that this case represents a new mutation.

Comment

Fetal cardiac tumors are rare. When symptomatic, they may present as (1) an arrhythmia secondary to a conduction defect or abnormal pacemaker function (as in our case), (2) nonimmunologic hydrops fetalis, or (3) death in utero from obstruction of blood flow by an intracavitary tumor. Tuberous sclerosis has been identified in up to one half of these patients and the diagnosis of fetal cardiac tumor should prompt a detailed ultrasound assessment to seek other abnormalities associated with this autosomal disorder, such as renal cysts or cerebral nodules. Pregnancy termination might be undertaken if multiple organ involvement is diagnosed early. In later pregnancy, if the fetus appears otherwise normal, hemodynamic impairment might dictate early delivery since neonatal resection of obstructive lesions has provided definitive therapy in several instances.[1] Whether tuberous sclerosis has occurred by new mutation or transmission from a carrier parent is crucial. In the latter instance, there is a 50% chance of recurrence in future offspring, with widely varying manifestations. For this reason, before embarking on future pregnancies, the parents should be offered prenatal genetic counseling, and during pregnancy, the previously described fetal assessment should be instituted.

This case and others illustrate that fetal cardiac tumors may present as arrhythmias and very often are markers for tuberous sclerosis.[2-4] Prenatal echocardiography may serve to define the arrhythmia, locate the tumor, and monitor hemodynamic changes.

FOR VULVOVAGINAL CANDIDIASIS

Think

vaginal cream 2.0%

Femstat®

(butoconazole nitrate)

FAST, SOOTHING RELIEF
Complete coverage–
and minimal vaginal leakage![1]

3-DAY THERAPY
As effective as miconazole cream–
in only 3 days' time!

3 DISPOSABLE APPLICATORS
Patient convenience and satisfaction–
for enhanced compliance!

*In non-pregnant patients, 3-day treatment is recommended. Treatment may be extended an additional 3 days, if necessary.

1. Droegemueller W, Adamson DG, Brown D et al: Three-day treatment with butoconazole nitrate for vulvovaginal candidiasis. *Obstet Gynecol* 64:530-534, 1984.

Please see brief summary of prescribing information on next page.

The Only 3-Day Cream*

Think

vaginal cream 2.0%

Femstat®

(butoconazole nitrate)

The Only 3-Day Cream

Brief Summary

INDICATIONS:
FEMSTAT® (butoconazole nitrate) vaginal cream 2.0% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS:
FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS:
General:
If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient:
Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis:
Animal studies have not been done.

Mutagenesis:
Mutagenicity studies were negative.

Impairment of Fertility:
Animal studies showed no impairment of fertility.

Pregnancy Category C:
Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers:
Use with caution.

Pediatric Use:
Safety and efficacy have not been established.

ADVERSE REACTIONS:
Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION:
Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

THE 1986 YEAR BOOK OF

OBSTETRICS AND GYNECOLOGY®

Edited by: Roy M. Pitkin, M.D., and Frank J. Zlatnik, M.D.

THE YEAR BOOK CONCEPT:

- Clinically oriented
- Condensations of the most vital journal articles worldwide chosen with your needs in mind—studies, discoveries, and developments that will affect your practice today. . .and tomorrow
- Pointed editorial comments on the articles—assessing their validity, relating them to other studies, and spotting new trends in the field
- A handsome, compact volume complete with illustrations, indexes, and references—a virtual storehouse of information enriching your professional library

1986 539 pp./229 illus. $42.95*

FREE ON 30-DAY APPROVAL!

Please rush me the following title for a free, trial examination:

*This book is published annually. For the convenience of its customers, Year Book enters each purchaser as a subscriber to future volumes and sends annual announcements of each volume approximately two months before publication. The new volume will be shipped upon publication unless you complete and return the cancellation notice attached to the announcement and it is received by Year Book within the time indicated (approximately 20 days after your receipt of the announcement). You may cancel your subscription at any time. The new volume may be examined on approval for 30 days, may be returned for full credit, and if returned Year Book will then remove your name as a subscriber. Return postage is guaranteed by Year Book to the Postal Service.

Prices quoted are in U.S. dollars. Canadian orders will be billed in Canadian funds at the approximate current exchange rate. A small additional charge will be made for postage and handling. Illinois and Tennessee residents will be billed appropriate sales tax. All prices quoted subject to change. Title marked (†) is forthcoming; please do not send cash for this book.

Maternal-Fetal Medicine

Hennepin County Medical Center and the University of Minnesota seek a faculty member to teach and conduct research in Maternal-Fetal Medicine. Candidates must have six years post M.D., board qualified or certified in Maternal-Fetal Medicine will be considered at the Assistant Professor level. Recruiting deadline is April 30, 1987.

Hennepin County Medical center and the University of Minnesota are equal opportunity employers and specifically invite and encourage applications from women and minorities.

Address inquiries to:

Bruce A. Work, Jr., M.D.
Professor and Head
Obstetrics and Gynecology
University of Minnesota
Box 395 UMHC
420 Delaware Street S.E.
Minneapolis, Minnesota 55455

UNIVERSITY OF GENEVA FACULTY OF MEDICINE

Applications are invited
for a tenured Faculty position at the
ASSOCIATE PROFESSOR (EXTRAORDINARIUS)
or
PROFESSOR (ORDINARIUS) level
in **Gynecological Endocrinology - Treatment of sterility**

The position is integrated in the Department of Obstetrics and Gynecology.

The appointee is expected to establish independent research in the area of reproductive endocrinology and treatment of sterility. The appointment starts on the 1st of October 1988.

Applicants should hold an M.D. degree with Board certificate or its equivalent. Application, including curriculum vitae, list of publications and a selection of 5-6 reprints (in 3 exemplars) should be sent to:

Secrétariat de la Faculté de Médecine
Hôpital cantonal universitaire
CH - 1211 GENEVA 4, Switzerland.

Closing date: May 1st, 1987.

FACULTY POSITION

The Department of Obstetrics and Gynecology at the University of Tennessee Medical Center at Knoxville, Tennessee is currently accepting applications for additional Maternal-Fetal Medicine Specialists.

These positions require Board certification or eligibility in Maternal Fetal Medicine. Responsibilities include: resident and medical student education, participation in Regionalization program and clinical or basic research.

Specialized areas of interest such as: critical care; ultrasonography and doppler studies; and prenatal diagnosis are encouraged. A private practice opportunity is available.

Academic rank is commensurate with qualifications and experience.

Interested persons should send curriculum vitae to:

Chairman, Department of
Obstetrics and Gynecology
University of Tennessee
Medical Center
1924 Alcoa Highway, U-27
Knoxville, TN 37920

For more information call

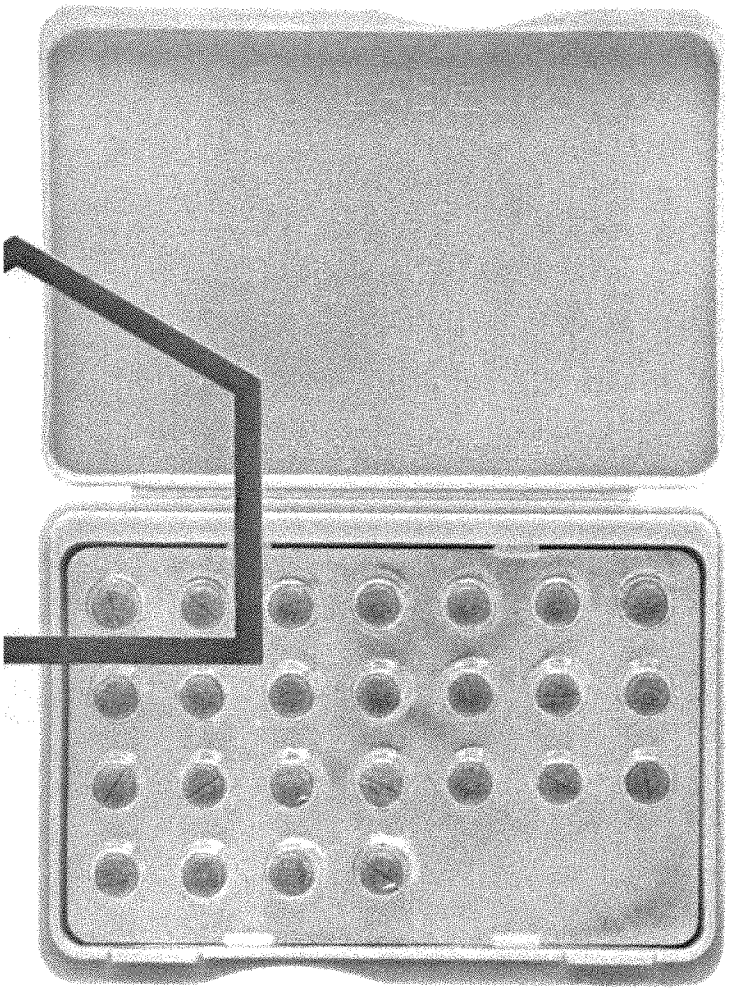
An Affirmative Action/Title IX/Section 504 Employer

OBSTETRICIAN/ GYNECOLOGIST
GREATER BOSTON OPPORTUNITY

Dynamic, highly motivated board eligible or board certified obstetrician/gynecologists sought to establish private practice in affiliation with a sophisticated 305 bed full service community teaching hospital 10 miles west of Boston. The ideal candidate will be one interested in a private practice supplemented by hospital based responsibilities. Generous financial assistance package is available to support the early years of practice. Position available immediately. Submit curriculum vitae and references to: Richard L. Brown, Executive Vice President and Chief Operating Officer, WalthamWeston Hospital & Medical Center, Hope Avenue, Waltham, MA 02254.

THE RIGHT CHEMISTRY



THE RIGHT REPLACEMENT FOR 17β-ESTRADIOL— 17β-ESTRADIOL

© 1986 Mead Johnson & Company • Evansville, Indiana 47721 USA MJL 5-4169

THE RIGHT REGIMEN

THE FIRST 25 DAYS OF THE MONTH— EVERY MONTH

ESTRACE is 17β-estradiol—just like the estrogen she made before menopause. Like the natural hormone, it follows a simple, well-known metabolic pathway, and it provides unsurpassed relief of postmenopausal vasomotor symptoms.

Micronized for good oral absorption, ESTRACE produces prompt, predictable serum levels of estradiol and estrone. Between cycles, ESTRACE is rapidly eliminated, providing estrogen replacement therapy that closely follows the premenopausal pattern . . . *for true cyclic therapy.*

Now it's in the ESTRACE Cycle Pak—an easy-to-carry compact, designed to deliver a starting dose of 2 mg in the preferred 25-day regimen. Cycle Paks delivering 1 mg daily are also available, if needed.

Mead Johnson LABORATORIES

For Brief Summary, please see following page.

ONLY NEW ESTRACE® (ESTRADIOL) TABLETS 1 mg and 2 mg CYCLE PAK HAS BOTH

ESTRACE® (estradiol)

TABLETS, 1 mg and 2 mg VAGINAL CREAM, 0.01%

Warning

1. **ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.** Three independent case control studies have shown an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for prolonged periods. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. **ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.** The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1000 exposures. Furthermore, a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb reduction defects. One case control study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed *in utero* to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. If ESTRACE® (estradiol) is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus and the advisability of pregnancy continuation.

Indications: *Tablets:* Moderate to severe *vasomotor* symptoms associated with the menopause (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause, and they should not be used to treat these conditions.); atrophic vaginitis; kraurosis vulvae; female hypogonadism; female castration; primary ovarian failure; breast cancer (for palliation only) in appropriately selected women and men with metastatic disease; prostatic carcinoma—palliative therapy of advanced disease. *Vaginal Cream:* Atrophic vaginitis and kraurosis vulvae. ESTRACE® HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

Contraindications: Known or suspected cancer of the breast, except in appropriately selected patients being treated for metastatic disease; known or suspected estrogen-dependent neoplasia; known or suspected pregnancy (See Boxed Warning); undiagnosed abnormal genital bleeding; active thrombophlebitis or thromboembolic disorders; a past history of thrombophlebitis, thrombosis or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

Warnings: Estrogens increase the risk of carcinoma of the endometrium (See Boxed Warning). Prescribe cautiously in women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms. A 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease has been reported in women receiving postmenopausal estrogens. There is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis or thromboembolic disorders or (except in treatment of malignancy) with a history of such disorders in association with estrogen use; they should be used with caution in patients with cerebral vascular or coronary artery disease and only for those in whom estrogens are clearly needed. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast, have been shown to increase the risk of nonfatal myocardial infarction, pulmonary embolism, and thrombophlebitis; when estrogen doses of this size are used, any of the thromboembolic and thrombotic adverse effects associated with oral contraceptives should be considered a clear risk. Hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Increased blood pressure occurs with use of estrogens in the menopause, and blood pressure should be monitored, especially with high doses. Diabetic patients should be carefully observed for decreased glucose tolerance. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases; if this occurs, the drug should be stopped and appropriate measures taken to reduce the serum calcium level.

Precautions: *General*—A complete medical and family history should be taken prior to initiation of therapy. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination. Conditions influenced by fluid retention, such as epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Undesirable manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc, may develop. Patients with a history of depression should be carefully observed. Pre-existing uterine leiomyomata may increase in size during estrogen use. Pathologists should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops, discontinue use while cause is investigated. Administer with caution in patients with impaired liver function, metabolic bone diseases associated with hypercalcemia, or renal insufficiency and in young patients with incomplete bone growth. The following endocrine and liver function tests may be affected by larger estrogen doses: increased sulfobromophthalein retention; increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability; increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay; free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered; impaired glucose tolerance; decreased pregnanediol excretion; reduced response to metyrapone test; reduced serum folate concentration; increased serum triglyceride and phospholipid concentration.
Information for the Patient—See text of Patient Package Insert.
Pregnancy Category X—See Contraindications and Boxed Warning.
Nursing Mothers—Administer to nursing mothers only when clearly necessary.
The 2-mg tablets contain FD&C Yellow No. 5 (tartrazine), which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals, frequently those who also have aspirin hypersensitivity.

Adverse Reactions: (See Warnings regarding induction of neoplasia, adverse effects on the fetus, increased incidence of gall bladder disease, and adverse effects similar to those of oral contraceptives, including thromboembolism.) The following additional adverse reactions have been reported: *Genitourinary system*—Breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis; change in cervical eversion and in degree of cervical secretion; cystitis-like syndrome. *Breast*—Tenderness, enlargement, secretion. *Gastrointestinal*—Nausea, vomiting; abdominal cramps, bloating; cholestatic jaundice. *Skin*—Chloasma or melasma which may persist when drug is discontinued; erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hair, hirsutism. *Eyes*—Steepening of corneal curvature; intolerance to contact lenses. *CNS*—Headache, migraine, dizziness; mental depression; chorea. *Miscellaneous*—Increase or decrease in weight, reduced carbohydrate tolerance, aggravation of porphyria, edema, changes in libido.

How Supplied: Tablets, containing 1 mg (lavender) and 2 mg (turquoise) micronized estradiol, in bottles of 100 and compacts of 25; Vaginal Cream, each gram containing 0.1 mg 17β-estradiol in a nonliquefying base containing purified water, propylene glycol, stearyl alcohol, white ceresin wax, glyceryl monostearate, hydroxypropyl methylcellulose, sodium lauryl sulfate, methylparaben, disodium edetate, and *t*-butylhydroquinone, in 1½-oz (42.5-g) tubes with calibrated plastic applicator for delivery of 1,2,3, or 4 g and in 1½-oz (42.5-g) refill tubes.

For Prescribing Information, please see physician package insert.

Mead Johnson LABORATORIES MJL 5-4169
MEAD JOHNSON & COMPANY • EVANSVILLE, INDIANA 47721 USA C-V14-12-85

THE UNIVERSITY OF ALABAMA AT BIRMINGHAM
DEPARTMENT OF OBSTETRICS AND GYNECOLOGY

Applications are invited by the Department of Obstetrics and Gynecology for an Assistant Professor position immediately. The applicant should possess a MD degree with laboratory training in experimental pathology, or a PhD degree in experimental pathology; experience in research and teaching required in general gynecologic investigations with strong emphasis in gynecologic oncology, pathology, cytology, tissue and serum markers. The applicant should possess substantial background in carrying out independent research, in coordinating multidisciplinary programs, and in supporting projects with residents and fellows in the Department. Please submit complete curriculum vitae and three letters of references to: Hugh M. Shingleton, MD, J. Marion Sims, Professor and Chairman, Department of Obstetrics and Gynecology, University of Alabama at Birmingham, Birmingham, Alabama 35294. The University of Alabama at Birmingham is an Affirmative Action/Equal Opportunity Employer.

POSITION AVAILABLE REPRODUCTIVE ENDOCRINOLOGIST

The Knoxville unit of the University of Tennessee's College of Medicine, Department of Obstetrics and Gynecology, seeks Board Eligible or Board Certified Reproductive Endocrinologists at Assistant Professor, tenure track level (higher level possible, depending on outstanding experience).

Successful candidate will have University funding for resident teaching, with ample opportunities for private practice development. Expansive practice opportunity developed and awaiting appropriate candidate. Experienced microsurgeon and interest in continuing development on an in-vitro fertilization program required. Opportunities available for scientific and clinical research related to reproductive endocrinology.

Interested persons should send curriculum vitae to:

Chairman, Department of Obstetrics and Gynecology,
University of Tennessee Medical Center
1924 Alcoa Highway, U-27
Knoxville, TN 37920
For more information call (615) 544-9306

An Affirmative Action/Title IX/Section 504 Employer

POSITIONS AVAILABLE

Two full-time positions are available for gynecologic oncologists in the Department of OB/GYN, U.C. Davis Medical Center, Sacramento, California. Applicants should be board certified in OB/GYN and knowledgeable in the areas of chemotherapy and radiation therapy. Applicants must demonstrate experience and competence in teaching and research related activities.

One position, for Associate/Assistant Professor requires the applicant to have successfully completed subspecialty training in gynecologic oncology, with subsequent specialty board eligibility and/or certification.

The second position, for Assistant Professor, requires the applicant to have completed subspecialty training in an approved program in gynecologic oncology.

Responsibilities include patient case management, surgery specific to gynecologic oncology, participation in teaching and development and/or participation in research activities and involvement in University and Hospital committees.

Send curriculum vitae and five references to:

Edward J. Quilligan, M.D.
Chairman, Department of Obstetrics and Gynecology
University of California, Davis, Medical Center
1621 Alhambra Boulevard, Suite 2500
Sacramento, California 95816

The final date for receipt of applications is "Open until filled, but not later than May 15, 1987."

The University of California is an equal opportunity, affirmative action employer.

WASHINGTON STATE MULTISPECIALTY GROUP PRACTICE

The Wenatchee Valley Clinic, a multispecialty group practice of 105 physicians seeks a Board Eligible/Board Certified OB/GYN physician to join its Moses Lake, Washington facility.

Moses Lake is in Central Washington State with close proximity to the Columbia River and the Cascade Mountain Range. The area is ideal for a family-oriented physician interested in the four-season recreational opportunities available.

Excellent professional environment with young, progressive group. Competitive salary and benefit package.

If interested submit CV to: E. Michael Graham, M.D., Moses Lake Branch of Wenatchee Valley Clinic, 840 E. Hill Ave., Moses Lake, Washington 98837.

TRI-LEVLEN

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

A LOW-DOSE TRIPHASIC OC WITH THE CONFIDENCE THAT COMES FROM EXPERIENCE

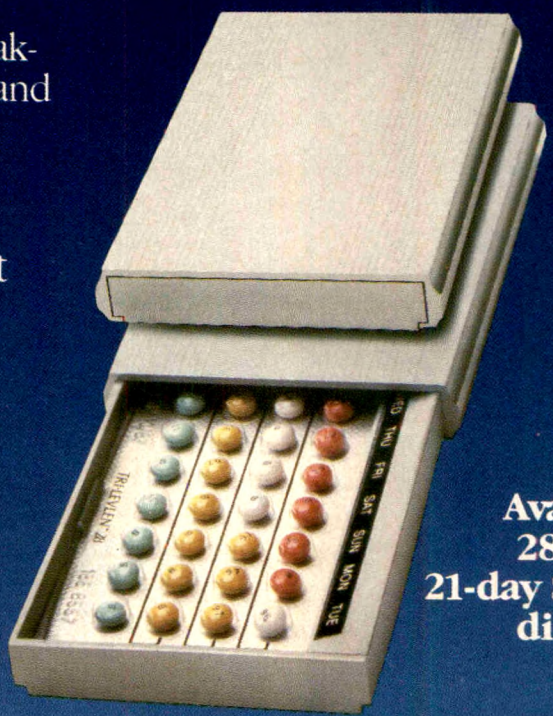
*Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. The physician should remain alert to the earliest manifestations of any symptom of serious disease and discontinue oral contraceptive therapy when appropriate. These d represent only the results of selected studies. Therefore, before prescribing, the physician should read and remain alert to all data found in the complete prescribing information for the product. Please also see brief summary of prescribing information on the last page of advertisement.

A formulation with the lowest total hormonal dose in a combination OC

Phased doses of both levonorgestrel and ethinyl estradiol

Permits a decrease in total steroid dose without compromising effectiveness.

Low incidence of breakthrough bleeding



A low 5.7% overall incidence of breakthrough bleeding based on 77 U.S. and U.K. studies involving 3,546 women (35,036 total cycles).[1]

Simple first dose/first day start

The first dose is taken on the first day of menstruation. No need to count days or wait for Sunday starts.

Minimal impact on the following metabolic and hemodynamic parameters*

Lipids;[2,3] carbohydrate metabolism[2,3] and blood pressure[1] were not significantly affected in certain specific studies.

A formulation with the confidence of 170 million cycles of experience worldwide

Available in 28-day and 21-day Slidecase™ dispensers

TRI·LEVLEN™ 28
TRI·LEVLEN™ 21

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

BRIEF SUMMARY

Tri-Levlen™—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxy-gon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.

4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.

5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.

7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.

9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.

10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient—See Patient Package Labeling

Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.

Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."

Nursing Mothers—See "Warnings."

Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.

There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted.: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.

For full details on dosage and administration see prescribing information and package insert.

Electromyographic observations on the human cervix during labor

Marjan Pajntar, M.D., Sc.D., Egidija Roškar, Sc.D., and Drago Rudel, M.Sc.
Kranj and Ljubljana, Yugoslavia

The activity of smooth muscles in the cervix is one of the relevant factors for its dilatation during labor, but in humans it has not yet been sufficiently studied. Muscular activity may be observed by measuring electromyographic phenomena. In 60 parturient women of different parity and with various degrees of cervical ripeness at the onset of labor, the cervical electromyographic activity was measured through the entire course of labor in synchronization with uterine pressure measurements and also in 30 cases in synchronization with measurements of the uterine corpus electromyographic activity. The conditions necessary for successful measurements are described. The intensity of the cervical electromyographic activity was found to decrease with the level of cervical ripeness and with parity. When measured in the longitudinal direction, the cervical electromyographic activity resembled that of the uterine corpus, but when picked up from the circular lead, in a few cases of unripe cervices it differed from the electromyographic activity of the uterine corpus. (Am J Obstet Gynecol 1987;156:691-7.)

Key words: Electromyography, cervix in labor

The opinion that the cervix is passive during labor and that its dilatation is due to contraction of the uterine corpus has lately been contested by a number of new findings. The latter pertain to histologic and biochemical changes in the cervix which make possible its efficient dilatation during labor,[1] as well as to the activity of cervical smooth muscles in mammals. The smooth muscles of the ewe's cervix contract vigorously even late in gestation and with the approach of parturition.[2] The cervical and uterine smooth musculatures appear to act independently, possibly reflecting their independent functioning.[2] In humans the factors responsible for efficient cervical dilatation during labor are independent of the factors responsible for efficient uterine contraction.[3]

Material and methods

The study involved 60 parturient women of various parity who were sent to the hospital for induced labor and therefore fulfilled the criteria for programmed labor.[4] In each patient the ripeness of the cervix was estimated according to the Bishop scores; after that an amniotomy was performed, a catheter for measuring intrauterine pressure was inserted, electrodes for detecting the electrical activities of the cervix and uterine corpus were attached, and within 30 minutes an oxytocin solution (Syntocinon) was administered by the drip method in a dose of 6.75 mEq/min. In a few exceptional cases Syntocinon was administered only later in the course of labor. "Partograms" were drawn in all the cases.

In the first 20 labors the detection of the cervical electromyographic activity was unipolar, in the 30 subsequent cases it was bipolar and single-lead (usually in the longitudinal direction), and in the last 10 cases both leads were used, a longitudinal and a circular one. The two-lead configuration is shown in Fig. 1. In 30 labors, a simultaneous bipolar recording of the electrical activity of the uterine corpus was also performed.

Surface Ag-AgCl disc electrodes were used to measure the abdominal uterine corpus electrical activity. They were attached 6 to 7 cm apart above the right or left horn of the uterus, with a reference ground electrode placed between the active electrodes. To obtain the electromyographic activity in the cervix, spiral electrodes, usually used to pick up fetal electromyographic activity, were adapted. These electrodes are standard accessories of the Hewlett-Packard HP 8030A cardiotocographic measuring set. A miniature two-channel differential electromyographic preamplifier was designed to amplify low-amplitude electromyographic potentials with the fixed gain of 1000 and a band width of 0.1 to 5 kHz (3 db). To diminish artifacts caused by body movements during labor, it was fastened to the upper part of a thigh by a belt to permit use of electrode wires that were as short as possible.

Electromyographic signals were further amplified by

a two-channel amplifier with an adjustable gain, an adjustable DC level, and a built-in low-pass filter (5 Hz). Electromyographic potentials were then recorded by a two-channel paper chart recorder which was a part of the above-mentioned cardiotocograph (1 minute = 10 mm). An adequate interface was made which enabled different combinations of simultaneous two-channel registrations.

Intrauterine pressure measurements were performed by means of an open-end saline-filled catheter and a pressure transducer.

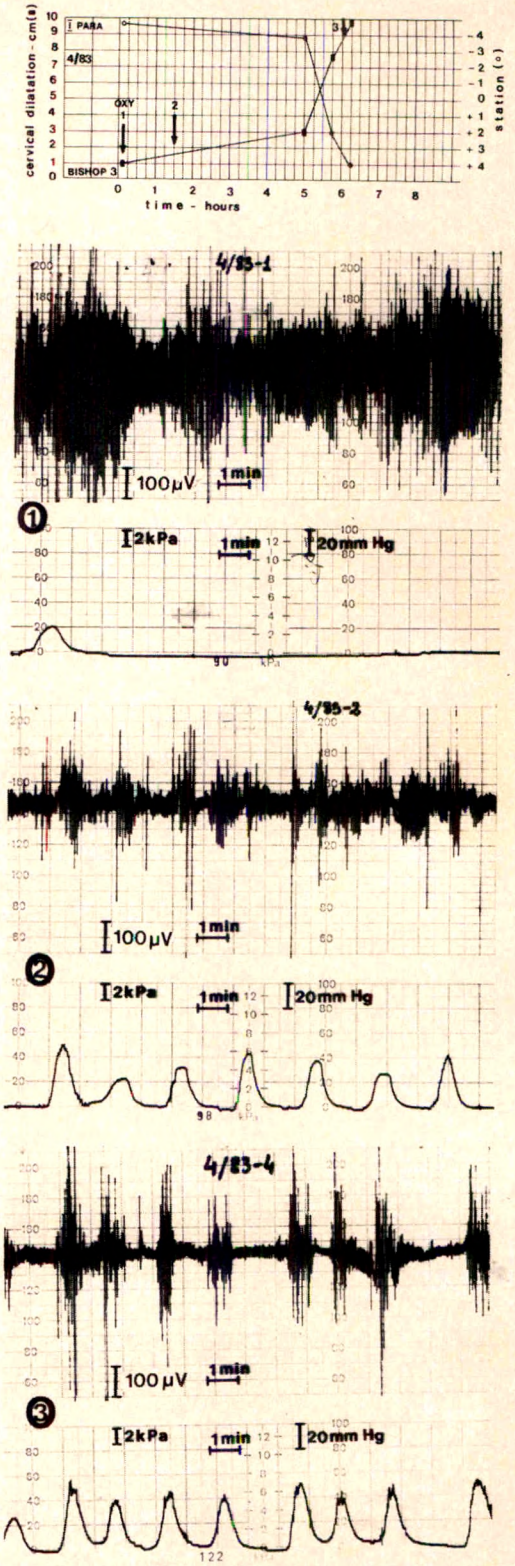

Fig. 3. Partogram, cervical electromyographic activity, and intrauterine pressure in a primiparous patient with unripe cervix. Parts *1*, *2*, and *3* correspond to the events marked in the partogram. For all parts, the upper trace = electromyographic activity and the lower trace = intrauterine pressure ("the basal tone" manually zeroed).

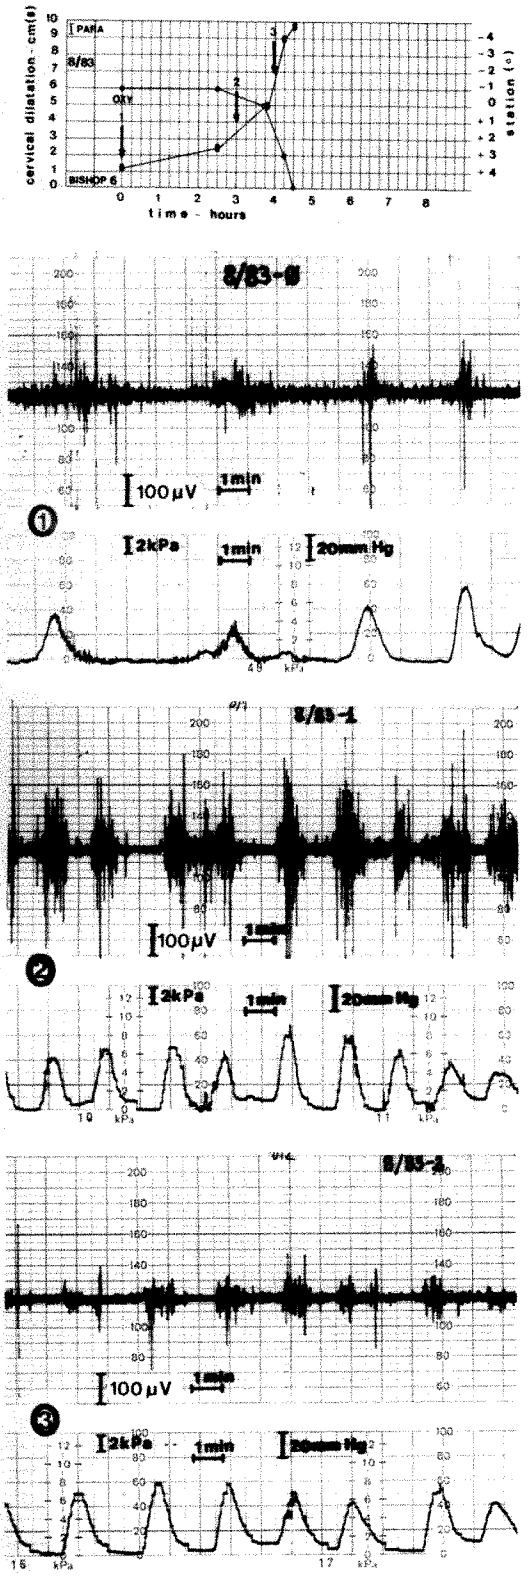

Fig. 4. Partogram, cervical electromyographic activity, and intrauterine pressure of a primiparous patient. Parts *1*, *2*, and *3* correspond to the events marked in the partogram. For all parts, the upper trace = electromyographic activity and the lower trace = intrauterine pressure.

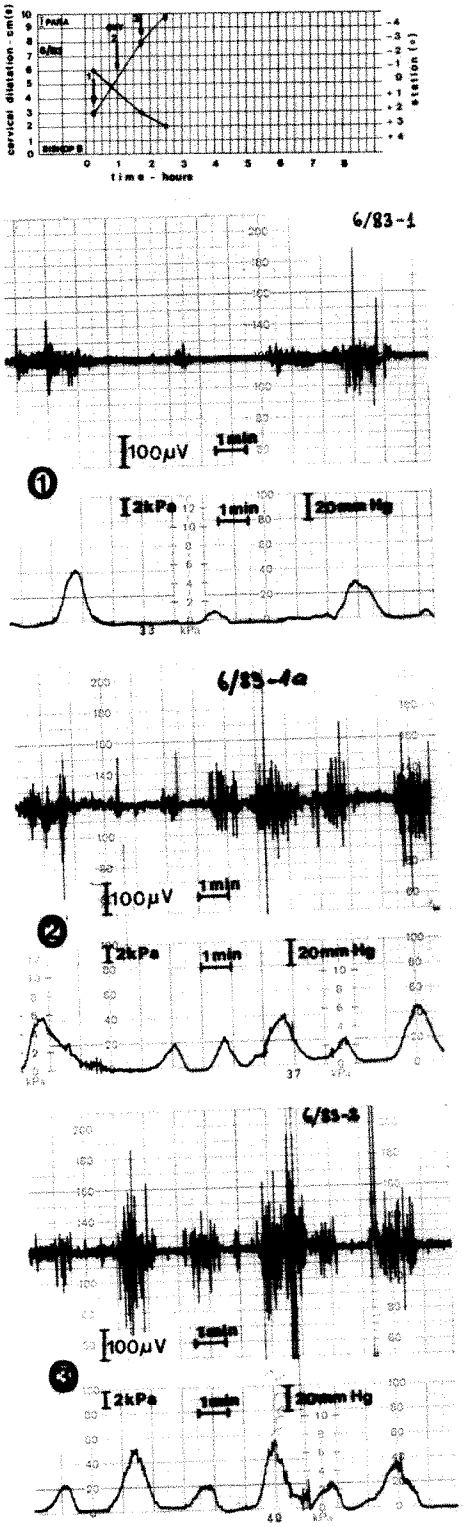

Fig. 5. Partogram, cervical electromyographic activity, and intrauterine pressure of a primiparous patient with ripe cervix. For all parts, the upper trace = electromyographic activity and the lower trace = intrauterine pressure.

Results

Forty-nine appropriate cervical electromyographic recordings were analyzed. They were performed in 28 primiparous women (23 with unripe cervices and 5 with ripe cervices) and in 21 multiparous women (10 with unripe cervices and 11 with ripe cervices). The peak-to-peak amplitude of the strongest burst of electromyographic signal was measured at a uterine contraction and between two contractions in the initial phase of labor—immediately after amniotomy and in the active phase after cervical dilatation of >6 cm. The mean values for each group are presented in Fig. 2.

In an attempt to describe the observed phenomena, typical segments of electromyographic recordings are presented below.

Ripeness of the cervix. The less ripe the cervix, the more intensive is its electrical activity during induced labor immediately after amniotomy (Figs. 3 to 5, *part 1*).

In unripe cervices a strong permanent activity is recorded at the beginning of the latent phase of dilatation, without any noticeable contractions of the uterine corpus (Fig. 3, *part 1*). This activity is subsequently grouped into increasingly pronounced bursts, which are usually synchronized with uterine contractions, but occasionally they also appear between two contractions (Fig. 3, *part 2*). In this period the activity occurring between two contractions is stronger than later in the active phase of dilatation. In riper cervices the initial activity is smaller and grouped into bursts, which occur in synchronization with uterine contractions but occasionally somewhat earlier or later (Figs. 4 and 5, *part 1*). In the active phase of cervical dilatation the activity appears to be grouped in bursts, usually in synchronization with uterine contractions and persisting throughout a contraction. The intensity changes in the course of labor. These changes are not always correlated to the intensity of uterine contractions (Fig. 4, *parts 2* and *3*). The activity, which is ungrouped at the onset of labor, groups and intensifies after administration of the oxytocin preparation. Weak electrical activity associated with infrequent contractions (Fig. 5, *part 1*) increases immediately after administration of oxytocin, and the frequency of contractions increases (Fig. 5, *parts 2* and *3*).

Parity. In principle, the intensity of the cervical electrical activity decreases with parity. Even in a patient who is para 2 with an extremely unripe cervix, electrical activity was observed similar to that found in primiparous patients with unripe cervices. In most cases, however, in secundiparous patients the electrical activity of the cervix bears more resemblance to that characteristic of primiparous women with ripe cervices (Fig. 5), although the cervical dilatation may be slower than in primiparous women with ripe cervices. In triparous and multiparous women the activity is smaller. As a rule, the amplitudes of individual bursts in multiparous women are much smaller. This type of minimal activity is exemplified here by the case of a triparous patient with a cerclage performed during pregnancy because of cervical insufficiency (Fig. 6). After oxytocin had been administered, uterine contractions became more frequent and stronger (Fig. 6, *parts 2* and *3*). The electrical activity appeared to be partly grouped in bursts of small amplitudes. The bursts occurred simultaneously with contractions as well as between two contractions, mostly with a nonuniform waveform and sequence, throughout the labor.

Electromyographic activity of the cervix and uterine corpus. The electromyographic activity of the uterine corpus was observed and compared to the electromyographic activity of the cervix. Because of the different types of measuring techniques implemented, the amplitude proportions between the two groups of results are of course only relative. The cervical electromyographic detection was unipolar and bipolar. After amniotomy the electrical activity in unripe cervices is usually greater than that in the corpus, whereas in the case of ripe cervices the situation is reversed. Later during labor, especially in the active phase of dilatation, the proportion between the two changes independently of the intensity of contractions. In the final phase of dilatation the intensity of electromyographic activity is usually smaller in the cervix than in the corpus (Fig. 7, *part b*). The cervical and uterine corpus electromyographic activities occur in groups of bursts, which are in most cases synchronized both with each other and with uterine contractions. In a few cases, however, the distribution of bursts along the time scale in the cervix is entirely different from that in the corpus (Fig. 7, *part a*).

Two-lead detection of the cervical electromyographic activity. The recording of the cervical electromyographic activity measured longitudinally and circularly are in most cases similar. However, in a few cases the electromyographic activity detected from the two leads differs, for example, in a primiparous woman with unripe cervix, Bishop score of 3 (Fig. 8). The differences are significant, especially in the latent phase of cervical dilatation (Fig. 8, *parts a* and *b*), whereas in the active phase of dilatation they diminish (Fig. 8, *parts c* and *d*). Immediately after amniotomy (Fig. 8, *part a*) the longitudinal activity is minimal. The circularly measured activity is stronger and is manifested as bursts of shorter or longer duration. After oxytocin has been administered (Fig. 8, *part b*), the longitudinal electromyographic activity intensifies. The increase is even greater in the circular direction. It is manifested in

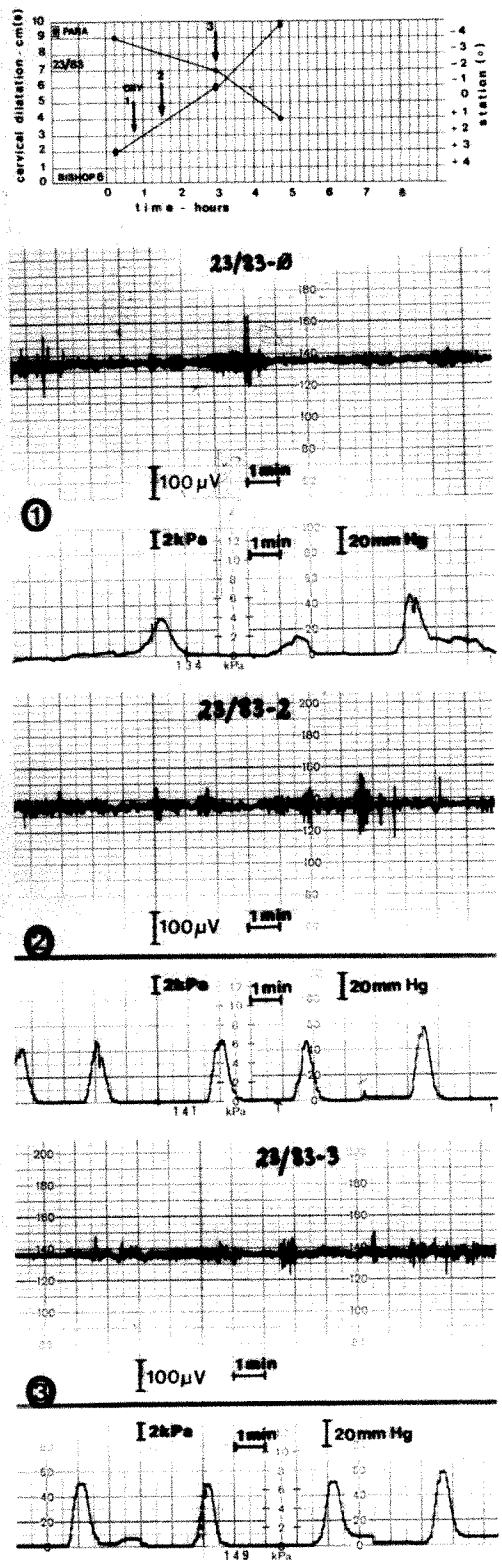

Fig. 6. Partogram, cervical electromyographic activity, and intrauterine pressure of a multiparous patient. Parts *1*, *2*, and *3* correspond to the events marked in the partogram. For all parts, the upper trace = electromyographic activity and the lower trace = intrauterine pressure.

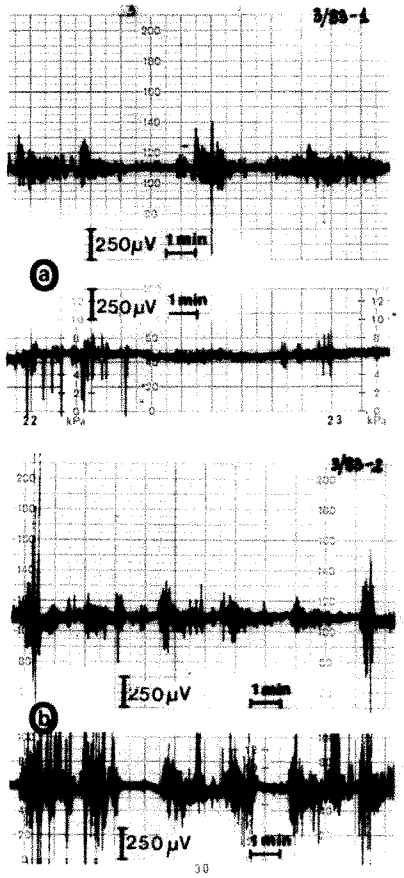

Fig. 7. Comparison of cervical and uterine corpus electromyographic activity measured at the beginning *(a)* and in the middle *(b)* of cervical dilatation in a primiparous patient. The upper trace = electromyographic activity of the cervix and the lower trace = electromyographic activity of the uterine corpus.

different shapes. The activity measured from both leads rapidly increases at the beginning of the active phase of dilatation (Fig. 8, *part c*). The longitudinal activity is relatively well grouped and synchronized with uterine contractions. The circular activity, however, is less well grouped. In the final phase of dilatation (Fig. 8, *part d*) a decrease in both activities is evident, particularly in the circular direction. At this stage the similarity and synchronization between the two activities is evident.

Comment

Adequate cervical dilatation is an important factor for a successful course of labor. The results of the measurements of the cervical electromyographic activity during labor confirm that also in the human the cervix is not just a passive part of the uterus but that its muscles also actively contract.

The results obtained so far primarily confirm the presence of electromyographic activity in the cervix

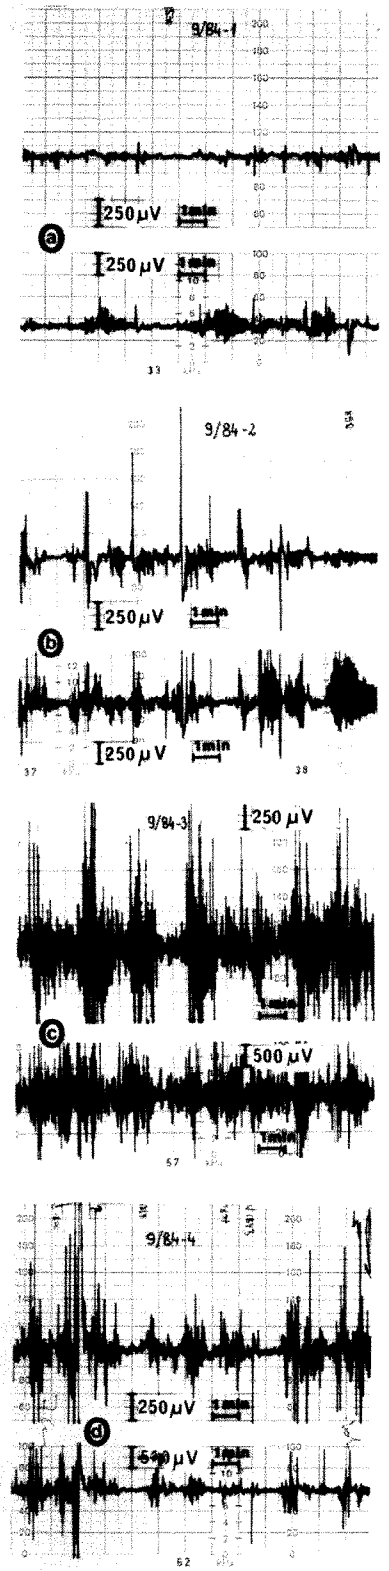

Fig. 8. Comparison of the cervical electromyographic activity measured from the longitudinal lead *(upper trace)* and from the circular lead *(lower trace)*. Part *a* = soon after amniotomy; part *b* = after oxytocin infusion; part *c* = at the 3 cm cervical dilatation; part *d* = final phase of dilatation.

during labor and establish the relevant conditions that have to be fulfilled to achieve efficient and high-quality recordings of this activity. They also suggest that this electromyographic activity appears in two directions, longitudinally and circularly.

The spiral electrodes used in our study to detect the cervical electromyographic activity served our needs well. It is important that they are firmly fixed in the tissue, which of course requires a certain amount of experience. In our first attempts the electromyographic recordings tended to be unreliable and of poor quality, especially toward the end of labor when the women grew restless and artifacts occurred because of movement of the electrodes in the tissues.

Another parameter tested in our investigation was the type of detection, which may be unipolar or bipolar. When unipolar detection was used, far more artifacts were found in the recordings. That is understandable, since such detection picks up the electrical potentials between the measuring electrode and the reference one and covers the potentials generated not only by the cervical muscles but also by all the structures between the two electrodes.

On the basis of the above findings resulting from our preliminary measurements, it was finally decided to use bipolar detection in our further work, since it yields the electrical activity between the two active electrodes inserted in the cervix.

At the initial stage of bipolar measurements of the cervical electromyographic activity, little attention was paid to positioning of the electrodes in terms of discriminating the electrical activity in the respective longitudinal and circular direction. As the difference between the electromyographic activity of the uterine corpus and that of the cervix was noticed, however, it led to the conclusion there might be differences in the electrical activity resulting from the use of different leads as well as from the activity of differently positioned muscle fibers (in the longitudinal and circular direction, respectively).

It was found that, in addition to the regular activity in the longitudinal direction, another, different activity in the circular direction occurs as well.

Because of the above-described course of our investigation, in most of our experimental cases the electrical activity of the longitudinal fibers of smooth cervical muscles was recorded. Their activity resembles that of the uterine corpus. This fact leads to the conclusion that these fibers may be excited by stimuli spreading downward from the corpus. The active contraction of the longitudinal fibers probably helps to shorten, open, and retract the cervix.

Our observations of the longitudinal electromyographic activity in the cervix agree with the findings of

some other authors[5] regarding the activity of smooth muscles in the uterine corpus: initially it is more nonuniform, and subsequently it groups into so-called bursts. The difference between the uterine corpus and the cervix activity exists in the fact that the electromyographic activity in the corpus normally anticipates the increase of the intrauterine pressure, whereas in the cervix it appears at the onset of contractions and persists throughout an entire contraction. The intensity of this activity varies in the course of labor quite independently of the intensity of the electromyographic activity of the uterine corpus and of the intensity of contractions. We therefore believe it is partly independent of the uterine corpus.

Particularly interesting is the circular electrical activity in the cervix, measured with the circular lead. This activity is entirely different from that found when recording from the longitudinal lead. It usually occurs in unripe cervices and in primiparous women at the beginning of labor and probably represents the circular muscle fiber activity. At present it can only be said that in all probability this activity does not exist in every woman, but that it is very important for the cervical tonus at the beginning of labor and that later it hinders effective dilatation of the cervical canal.

Visual evaluation of recorded electromyographic activity without more subtle subsequent analyses does not permit more precise description of the electrical phenomena in the cervix during labor. Recent advances in computer analyses of bioelectrical signals make their quantitative explanation possible. Spectral analysis has been implemented for this purpose, and the changes in typical frequencies in the power density spectral function of the cervical electromyographic signal were studied. The results are encouraging in helping to differentiate the contribution of the two types of muscle fibers in the cervix to its efficient dilatation during labor. It is hoped that we will be able to identify the differences between the electromyographic activity of the cervix and that of the uterine corpus.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Significant bacteremia associated with replacement of intrauterine contraceptive device

Sarah Murray, B.M., J. B. Hickey, M.A., B.M., B.Ch., and Elizabeth Houang, M.B., Ch.B.
London, England

Blood culture samples were taken from 23 women at different stages when an intrauterine contraceptive device was replaced. Transient bacteremia resulting from vaginal organisms was found in 13% of women 4 to 6 minutes after insertion of the new device. Previous reports have failed to demonstrate bacteremia associated with either first insertion or removal of intrauterine contraceptive device. Our results show that replacement of an intrauterine contraceptive device, a more traumatic procedure, causes significant bacteremia, and chemoprophylaxis should be given to patients in the groups at risk. (AM J OBSTET GYNECOL 1987;156:698-700.)

Key words: Bacteremia, vaginal; intrauterine contraceptive device; chemoprophylaxis

The process of inserting an intrauterine contraceptive device involves intracervical instrumentation, which might be expected to introduce vaginal bacteria into the uterine cavity and provide a source for potential bacteremia. Major complications after such a procedure have been reported in certain high-risk groups of patients; these include bacterial endocarditis in patients with valvular heart disease and overwhelming septicemia in immunosuppressed patients.[1, 2] It has therefore been recommended that patients with a prosthetic heart valve should receive antibiotic prophylaxis for the insertion or removal of an intrauterine contraceptive device.[3]

Despite the theoretical risk of bacteremia, previous studies designed to assess the incidence of its occurrence have failed to demonstrate significant bacterial growth in blood cultures taken after either insertion or removal of the device.[4, 5]

It is now common practice for many women to have their intrauterine contraceptive devices changed at regular intervals by their own general practitioner. We wished to study the incidence of significant bacteremia after the routine replacement of an intrauterine contraceptive device in the doctor's office, so that the potential risk could be assessed and become more widely known among doctors offering this service.

Patients and methods

Patients of one medical practice were studied. These were patients for whom a change of intrauterine contraceptive device was due, and for whom the device continued to provide an appropriate method of contraception. The patient was allocated the replacement intrauterine contraceptive device (Nova T or Gravigard) according to the randomized code.

The old intrauterine contraceptive device was first removed under the vision of a sterile bivalve speculum with the long-handled forceps. The next procedure was a bimanual examination to exclude cervical or adnexal tenderness. The cervix was again exposed and swabbed with a disinfectant (Sartodil, ICI) three times with the aid of a vulsellum applied to the anterior lip of the cervix. The new intrauterine contraceptive device was then inserted according to the technique recommended by the manufacturer. All patients were seen 6 weeks after the replacement of the intrauterine contraceptive device for a check-up appointment. Throughout the procedure, aseptic nontouch technique was used with gloved hands by the operator. The gloves were changed after the bimanual examination.

Blood samples were obtained from an intravenous sampling catheter (Wallace Y Can 2/g) inserted into a forearm vein after the skin was disinfected with 70% isopropyl alcohol. Samples (20 ml) were obtained as control at the start of the procedure, after removal of the old coil, and at approximately 2, 5, 7, and 10 minutes after insertion of the new coil. Sterile normal saline solution, 0.9%, was used to flush the cannula between samples. Each blood sample was immediately injected into a set of blood culture bottles consisting of a Digest Broth with 0.1% glucose and Liquoid (Southern Group Laboratories) and a Fastidious Anaerobic Broth containing thymidine (LAB M). The blood culture bottles were incubated within 3 hours and processed in a routine manner by the microbiology department of the Chelsea Hospital for Women.

Table I. Bacterial isolates from the blood cultures obtained during the replacement of intrauterine contraceptive devices

Patient No.	*Time interval when positive culture was obtained*	*Bacterial species*
1	After removal of Copper-7	*Staphylococcus epidermidis* and nonhemolytic streptococcus
2	After removal of Multiload	Anaerobic diphtheroid
3	7 min after insertion	*Bacteroides* sp.
4	4 min after insertion	*Gardnerella vaginalis*
5	5 min after insertion	*G. vaginalis*
6	10 min after insertion	*S. epidermidis*
7	7 min after insertion	*S. epidermidis* and anaerobic diphtheroid
8	4 min after insertion	*S. epidermidis* and diphtheroids
9	2 min after insertion	Anaerobic diphtheroids

Results

Twenty-three women were studied: 12 received a Gravigard intrauterine contraceptive device and 11 a Nova T device. All new devices remained satisfactory at the follow-up appointment with no evidence of adnexal infection during the bimanual examination.

A total of 138 blood culture sets were examined from the 23 patients. Bacterial growth was observed in 13 blood culture sets from 10 women. All the control blood cultures were negative except for one patient in whose sample bottle *Staphylococcus epidermidis* grew. The details of the positive cultures from the other nine patients are shown in Table I. There was no significant correlations between the likelihood of bacteremia and the parity of the women, the duration of use of the old intrauterine contraceptive device, and the type of the new device.

Comment

Throughout the procedures, nontouch aseptic technique was used with gloved hands. The blood samples were drawn from the intravenous catheter in the forearm either by the nurse not involved in the procedures or by the operator herself with the gloves removed. It is therefore unlikely that the blood samples would be contaminated by organisms from the vagina. Of the bacterial species isolated, *Gardnerella vaginalis* and *Bacteroides* may be assumed to be of vaginal origin, since they are normally found in the vagina but not on the skin, whereas the other species are commonly found from both sites.[6] Thus the incidence of bacteremia of vaginal origin is at least 13% (3/23). All cases occurred transiently 4 to 6 minutes after insertion of the new intrauterine contraceptive device, that is, after three different gynecologic procedures: removal, bimanual examination, and insertion. The summation of these procedures may increase the chance of a positive culture. In contrast, the negative findings reported by other workers were based on blood culture studies performed during the first insertion or removal of an intrauterine contraceptive device. Everett et al.[4] examined aerobic blood cultures obtained before and at various intervals up to 1½ hours after intrauterine contraceptive device insertion in 84 women and after removal of the device in 16 women. They did not find significant bacterial growth other than isolated positive cultures resulting from skin contaminants, although they did not report that anaerobic blood culture studies were performed. These authors therefore concluded that chemoprophylaxis during insertion or removal of an intrauterine device would be unnecessary in the absence of evident pelvic infections. Hall et al.[5] also failed to demonstrate bacteremia in blood cultures obtained from 25 women before and within 3 to 8 minutes of intrauterine contraceptive device insertion.

At the time of intrauterine contraceptive device replacement, none of our patients had symptoms or signs of pelvic infection, which has been reported to occur in 2.5% of patients in the first year of use of the device.[7] All the devices involved in our study were of the tailed type. Sparks et al.[8] demonstrated the presence of a small number of bacteria in the uterine cavity long after insertion of a tailed device. Jacques et al.[9] showed that in experimental rabbits, microorganisms colonized the core surface of both the tailed or untailed devices if they were inserted via the cervix. We did not perform a culture of the removed device, since it was difficult to avoid contamination with vaginal flora during the retrieval procedure. It is therefore uncertain whether bacteremia demonstrated in our study was associated with an infected/colonized device. It is reasonable to assume that the chance of having a positive blood culture would be increased by replacement of the device in an uterus already colonized by vaginal organisms.

Almost half a million women currently use the intrauterine contraceptive device in the United Kingdom, and replacement of the device is becoming a commonly performed procedure, often in the general practice. The risk of bacteremia associated with a first insertion or removal of the device may be very slight.[4, 5] The results of our study, however, show that replacement of the device is associated with bacteremia of vaginal

origin, with an incidence of at least 13%, thus lending support to the cautious attitude expressed by Sparks.[10] If it is deemed necessary on balance to fit an intrauterine contraceptive device in a woman who has prosthetic heart valves, had previous cardiac surgery, or is a drug abuser, antibiotic cover for insertion and replacement should be mandatory and follow-up should be performed at a hospital-based clinic where sterilized instruments are available. An absolute contraindication should be a history of pelvic inflammatory disease or infective endocarditis. To minimize the risks of bacteremia, one should also consider the use of an intrauterine contraceptive device licensed for 4 to 5 years and perhaps carry out the removal and insertion of the device at different clinic appointments.

We thank Schering Pharmaceuticals for the grant to cover the cost of material and transport of specimens.

Measurement of antibody to *Mycoplasma hominis* by an enzyme-linked immunoassay and detection of class-specific antibody responses in women with postpartum fever

Mary B. Brown, Ph.D., Gail H. Cassell, Ph.D., William M. McCormack, M.D., and Jerry K. Davis, D.V.M., Ph.D.

Gainesville, Florida, Birmingham, Alabama, and Brooklyn, New York

The standard conditions for detection of human IgG, IgM, and IgA antibodies to *Mycoplasma hominis* by an enzyme-linked immunosorbent assay (ELISA) were established with the use of a cell lysate antigen and alkaline phosphatase conjugates. Antigen was used at a concentration of 10 μg of protein per milliliter, sera were diluted 1:200, and conjugates were diluted 1:500. Agreement between cultured isolation of *M. hominis* from the lower genital tract and presence of antibody in 207 women was 71%, 82%, and 86% for IgG, IgM, and IgA, respectively. When the ELISA was compared with the mycoplasmacidal assay, an overall agreement of 81% occurred, with the majority of the discrepancies occurring in the ELISA-positive and mycoplasmacidal-negative category. A linear relationship between end point titer and the A400 value (ELISA or absorbance value at 400 nm) at a standard serum dilution was demonstrated for the IgG, IgM, and IgA classes. Although the ELISA was relatively independent of antigen heterogeneity, no single strain detected more than 87% of positive sera, thus suggesting that optimum detection of antibody to *M. hominis* by the ELISA will require use of antigen pools derived from multiple strains of *M. hominis*. (Am J Obstet Gynecol 1987;156:701-8.)

Key words: *M. hominis*, ELISA, class-specific antibodies, postpartum fever

Depending on a number of factors, including age, sexual experience, and socioeconomic background, *Mycoplasma hominis* can be isolated from the lower genitourinary tract in up to 53.6% of healthy adults. However, carefully controlled cultural and serologic studies suggest that under certain circumstances this opportunistic microorganism is capable of invading the upper genitourinary tract and is of etiologic significance in postpartum fever, salpingitis and pyelonephritis.[1] *M. hominis* can also cause amniotic fluid infection, meningitis, submandibular adenitis, and subcutaneous abscesses in neonates and has been implicated in congenital pneumonia.[1,2]

The commensal nature of *M. hominis* in normal individuals necessitates that definitive diagnosis of disease must depend not only on cultural isolation but also on appropriate clinical manifestations in conjunction with acute and convalescent serology.[1] A variety of serologic methods have been used for detection of antibody to *M. hominis;* all have technical difficulties. The hemagglutination inhibition test is the most sensitive but is difficult to standardize. The metabolism inhibition assay is fairly easy to perform, but the time at which the assay is read is a major cause of nonreproducibility of results. In addition, it is less sensitive than hemagglutination inhibition, and there is little correlation between the two tests. The mycoplasmacidal test may be more sensitive than metabolism inhibition but sensitivity and specificity are affected by many factors, including antigen concentrations and complement activity.

The enzyme-linked immunosorbent assay (ELISA) has been applied to the detection of antibodies against other mycoplasma species and has been found to be a rapid, reliable, and sensitive means of diagnosis. The objectives of the present study were to establish an ELISA for detection of class-specific antibody to *M. hominis* and to compare its efficacy to that of an established serologic assay for detection of antibody responses. Because of the documented etiologic significance of *M. hominis* in postpartum fever, comparisons were made with the use of sera from patients with postpartum fever.

Material and methods

Mycoplasma strains. Reference strains of *M. hominis* PG21 and *M. pneumoniae* FH-Liu were obtained from

From the Department of Infectious Diseases, University of Florida, the Departments of Microbiology, Biology, and Comparative Medicine, University of Alabama in Birmingham, and the Division of Infectious Diseases, Downstate Medical Center.

Supported by Research Grants HD 11447 and HD 16199 to Dr. Gail H. Cassell from the National Institute of Child Health and Human Development and P60 AM 20614 to Dr. Gail H. Cassell from the National Institute of Arthritis, Metabolism, and Digestive Diseases.

Received for publication April 1, 1986; revised September 11, 1986; accepted October 16, 1986.

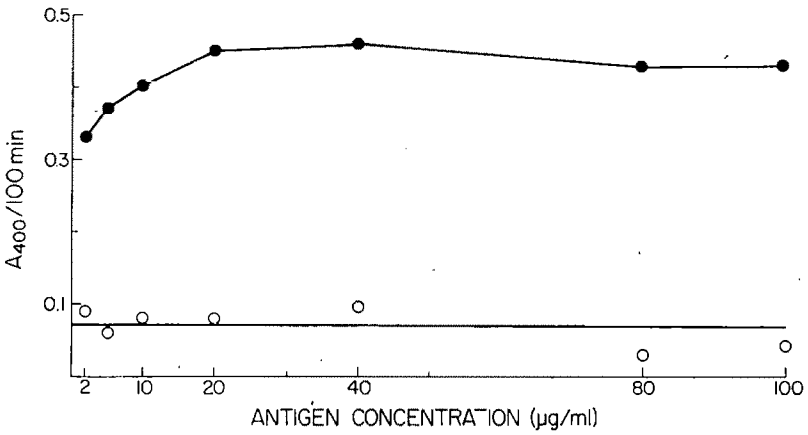

Fig. 1. Effect of *M. hominis* PG21 antigen concentration. Tubes were coated 4 hours, at 37° C, and evaluated with human immune (●) and normal sera (○) diluted 1:200. Anti-IgG conjugate was diluted 1:500.

Table I. Standard ELISA conditions for detection of human antibodies to *Mycoplasma hominis*

ELISA reagent	*Concentration**	*Diluent†*	*Incubation time*	*Incubation temperature*
Antigen	10 μg protein/ml	CBB	4 hr	37° C
Serum	1:200	PBSTA	5 hr	Room temperature
Conjugate	1:500 (IgG, IgM), 1:250 (IgA)	PBSTA	Overnight	Room temperature
Substrate	1 mg/ml‡	SB	30 min (IgG), 1 hr (IgM, IgA)	37° C

*All concentrations are dependent on lot number of conjugate and antigen used and should be reevaluated for each new lot of reagent.

†CBB = 0.1 mol/L sodium carbonate buffer, pH 9.6; PBSTA = phosphate-buffered saline with 0.05% Tween 20 and 0.02% sodium azide; SB = 0.05 mol/L sodium carbonate buffer, pH 9.8, with 0.001 mol/L magnesium chloride.

‡Alkaline phosphatase substrate tablets (Sigma Chemical Company, St. Louis, Missouri).

Research Resources Branch, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland. Six additional strains of *M. hominis* were obtained from J. S. Lin, Channing Laboratory, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, and have been described previously.[3, 4] Serotypes 1 to 8 of *Ureaplasma urealyticum* were obtained from E. A. Freundt, Institute of Medical Microbiology, University of Aarhus, Aarhus, Denmark. Glucose fermenters were grown in basal liquid medium, while non–glucose fermenters were cultivated in Shepard's liquid 10B medium supplemented with arginine (0.2% final concentration).

ELISA antigens. Ten milliliters of each microorganism in logarithmic growth (12 to 20 hours, 10^5 to 10^8 cfu/ml, dependent on mycoplasma strain) was diluted in broth (1:15 to 1:20) and harvested by centrifugation at 10,000 × g for 30 minutes at 4° C after a color change (12 to 20 hours). The pellet was resuspended and washed three times with sterile phosphate-buffered saline, pH 7.3. Bacterial contamination was monitored by inoculation of tryptic soy and blood agar plates. The washed pellet of cells was resuspended in phosphate-buffered saline (5 mg of protein per milliliter) and lysed by addition of 0.05 mol/L carbonate-bicarbonate buffer, pH 10.0, at 37° C, as described by Horowitz and Cassell.[5] The protein content of each lysate was determined, and all antigens were stored at −70° C.

Standard human reference sera. The human "immune" standard used was a pool of 15 sera from individuals known to be serologically positive in either the metabolism inhibition or mycoplasmacidal assay for *M. hominis* and culturally positive for *M. hominis* in the lower genital tract (cervix-vagina). The normal human serum used in the standardization assays was a single serum available in large quantity with an ELISA value <1 SD from the mean of 40 sera obtained from culturally negative individuals.

Clinical serum samples. Paired acute and convalescent phase sera from 11 women and five unpaired serum samples (one acute, four convalescent) from patients with postpartum fever of documented mycoplasmal origin that have been described previously[6, 7] were analyzed. Serum samples were collected at the time of delivery and 4 to 6 weeks post partum. Sera were heat inactivated at 56° C for 30 minutes and stored at −20° C. The antibody titers in these 27 sera were determined by J. S. Lin with the complement-depen-

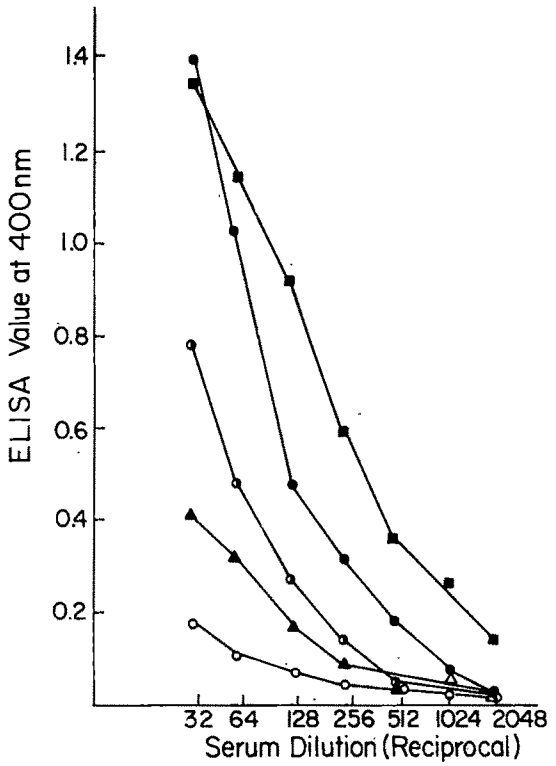

Fig. 2. Effect of serum dilution on detection of IgG in positive (●, ■, ◑, ▲) and negative (○) sera.

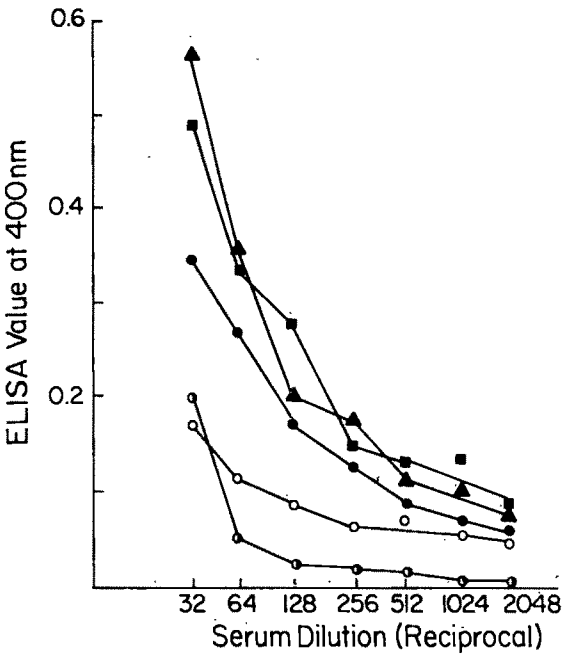

Fig. 3. Effect of serum dilution on detection of IgM in positive (▲, ■, ●) and negative (◑, ○) sera.

dent mycoplasmacidal test[4] and some have been previously reported.[7]

For comparative purposes, acute and convalescent serum pairs from six patients with nongonococcal urethritis of presumed ureaplasmal origin[8] were obtained from M. C. Shepard, Camp LeJeune Naval Hospital, Jacksonville, North Carolina.

In order to determine correlation between serology and culture, serum and cervicovaginal cultures were obtained as described previously[9] from 207 women undergoing laparoscopy for diagnosis of infertility (169 patients) or laparoscopy for tubal ligation (38 patients).

Four reference sera with known complement fixation titers to *M. pneumoniae* were provided by the Alabama State Board of Health Laboratory, Montgomery, Alabama.

Enzyme-conjugated anti-immunoglobulins. Alkaline phosphatase conjugates (Flow Laboratories) to human heavy γ-chain, μ-chain, and α-chain were used to detect the IgG, IgM, and IgA response, respectively. Conjugates were stored at 4° C and diluted immediately before use.

Detection of antibody. Incubation times and concentrations of antigen, conjugate, and serum were determined by checkerboard titration as described previously.[8] Before each addition, antigen-coated tubes were washed three times with 0.9% sodium chloride containing 0.05% Tween 20. All additions were in 1 ml volume. A background control in which phosphate-buffered saline containing 0.05% Tween 20 and 0.02% sodium azide was substituted for serum was included in each assay. Initially, a control tube coated with sterile 10B medium was included to test for nonspecific reaction to medium components, including reactions to yeast extract and horse serum. This control was always negative and was excluded from later assays. The reaction was stopped by addition of 0.1 ml of 1N sodium hydroxide and the absorbance determined at 400 nm.

End point titer analysis. Sera from randomly selected patients with postpartum fever were diluted twofold and tested in the ELISA. The reciprocal of the last dilution to give an A400 value >0.1 was deemed the end point titer. The end point titer versus the A400 value (absorbance value at 400 nm) at the 1:128 dilution was plotted to give a standard regression line.

Statistical analysis. Results were analyzed with a computer-assisted statistical analysis system. The Spearman rank order correlation coefficient, Pearson product moment correlation coefficient, Kruskal-Wallis test, and χ^2 test for independence with Yates' correction factor were used where appropriate.

Results

Standard assay conditions. The standard conditions established by checkerboard titration and chosen for the ELISA are given in Table I. The optimum antigen concentration for detection of IgG antibodies against *M. hominis* was 20 μg of protein per milliliter (Fig. 1).

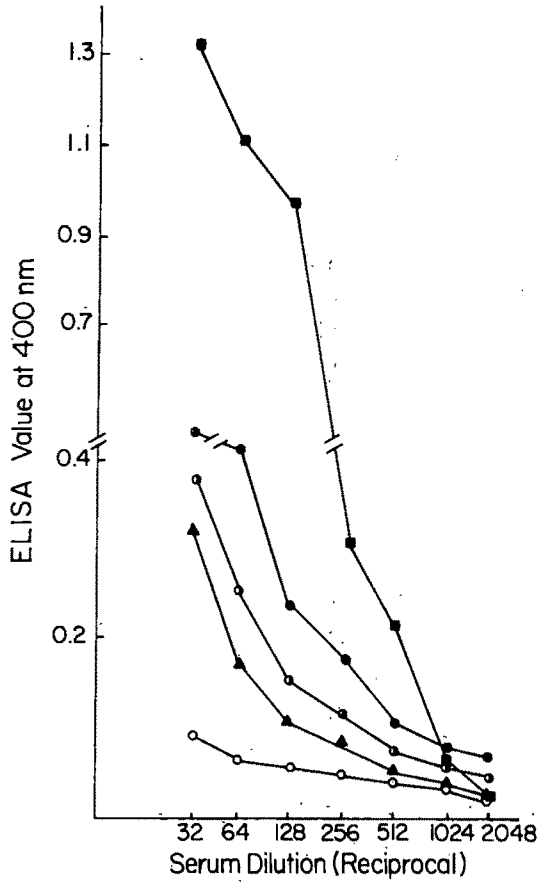

Fig. 4. Effect of serum dilution on detection of IgA in positive (■, ●, ◑, ▲) and negative (○) sera.

Similar results were found for IgM and IgA (data not shown). Since lower concentrations of antigen gave adequate differentiation between human immune and normal human serum standards, 10 μg of protein per milliliter was chosen to conserve antigen and to avoid problems associated with oversaturation of binding sites.[10] The effect of serum dilution at the standard antigen and conjugate concentration is shown for IgG (Fig. 2), IgM (Fig. 3), and IgA (Fig. 4). The serum dilution of 1:200 was selected as the standard dilution since it appeared to be near the midpoint of the curves for all three antibody classes.

Assay reproducibility. Twenty-nine samples were assayed twice (6 weeks apart) with the use of IgG conjugate with a correlation coefficient of 0.939 ($p < 0.001$). In addition, the SD of the normal human serum and human immune standards was determined on the basis of a minimum of 12 assays during a 5-month period. The SD for normal human serum was 0.038 with an SE of 0.01, and for human immune, 0.114 with an SE of 0.03. Similar results were obtained for the IgM and IgA classes.

Assay specificity. Human reference sera with known complement fixation titers (range 32 to 128) to *M. pneumoniae* did not react with the *M. hominis* ELISA antigen (<0.13 optical density). All *M. pneumoniae* reference sera reacted in the ELISA (>0.300 optical density) with *M. pneumoniae* antigen.

Because *M. hominis* is frequently coisolated with *U. urealyticum*, sera from 207 women were assayed in both the *M. hominis* and *U. urealyticum*[8] ELISAs to determine if any correlation in ELISA levels occurred. Individuals who were infected with ureaplasma but not *M. hominis* had significantly lower IgG ($p < 0.03$) and IgA ($p < 0.04$) (Kruskal-Wallis test) levels to *M. hominis* antigen. In addition, correlation coefficients between the two assays were low for IgG (<0.20) and IgA (<0.5), suggesting no significant cross-reactions. In the IgM class, a higher correlation (0.74) was observed. As would be predicted, the strongest correlation of IgM levels occurred in those individuals colonized by both *M. hominis* and *U. urealyticum* with no apparent cross-reactions in individuals with only one microorganism.

Finally, to determine if the presence of antibody to ureaplasma influenced detection of antibody titer changes; 12 acute and convalescent serum pairs were analyzed with the use of both the *M. hominis* and ureaplasma ELISAs. Six paired sera were from nongonococcal urethritis patients[8] and six were from patients with postpartum fever. Two individuals demonstrated changes in levels to both antigens; however, one decreased in titer to ureaplasma while increasing in titer to *M. hominis*. For the remaining individuals, all antibody changes were to a single microorganism even when specific antibody to the other microorganism was present.

Correlation of cultural isolation and ELISA. The agreement between cultural isolation and ELISA serology in 207 women is given in Table II. The best overall agreement was seen in the IgA class. In the IgG class, 48 of the 59 discrepancies (81%) were due to culturally negative, seropositive individuals. In the IgA class, however, 71% of the discrepancies were a result of culturally positive, seronegative individuals. Therefore, a positive serology in the absence of cultural isolation occurred most frequently in the IgG class ($p < 0.03$). A positive serology in the absence of cultural isolation rarely occurred in the IgA class ($p < 0.001$); further it was not uncommon to have cultural isolation in the absence of an IgA response.

Comparison of mycoplasmacidal and ELISA tests in postpartum fever patients. Twenty-seven individual sera (11 paired, one acute, and four convalescent) were evaluated. A serum sample was considered positive if the ELISA value was >2 SD above the normal serum value or if the mycoplasmacidal titer was ≥32. Eighteen and four sera were positive and negative, respectively, by both tests for an overall agreement of 81.5%. Four (14.8%) sera were positive by ELISA but negative by

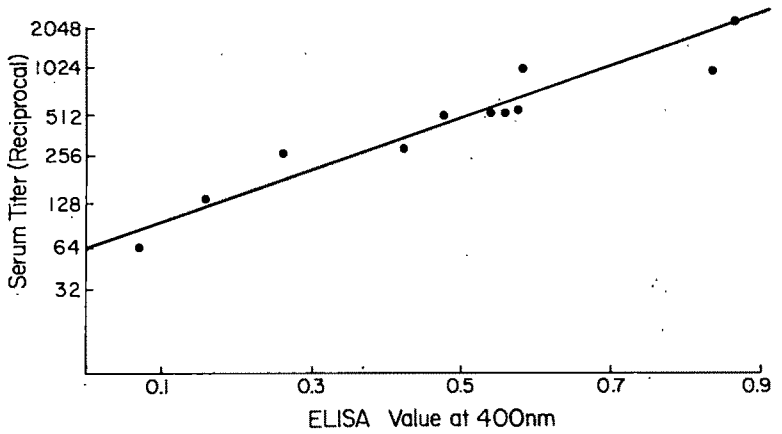

Fig. 5. Correlation of end point titer with ELISA A400 value for IgG. The reciprocal of the last dilution to give an A400 value ≥0.100 was deemed the end point titer. The end point titer for a serum was plotted versus the A400 value of the 1 : 128 dilution of that serum.

Table II. Agreement between cultural isolation of *Mycoplasma hominis* from the lower genital tract and presence of antibody in 207 women

Antibody class	*Culture positive (N = 45)*				*Culture negative (N = 162)*				*Total agreement*

‡Antibody class least likely to have seropositive but culture-negative individuals ($p < 0.001$).

mycoplasmacidal titer. Only one mycoplasmacidal-positive serum sample was not detected by ELISA.

Results obtained in the mycoplasmacidal test were dependent on the strain used as antigen whereas the results obtained by ELISA were relatively independent of the strain used as antigen (Table III). No single strain allowed detection of >40% of the positive sera when used in the mycoplasmacidal test. Although no statistically significant differences were found among *M. hominis* strains when used as ELISA antigens, strains PG21 and 4195 appeared to be the best antigens with 87% and 83% detection, respectively. For comparative purposes, *M. hominis* PG21 was chosen as the standard ELISA antigen and gave a high degree of correlation with results obtained for *M. hominis* strain W2 ($p < 0.04$) and all other strains tested ($p < 0.001$). All mycoplasmacidal-positive serum samples except 23 (Table III) could be identified with a combination of three strains (PG 21 and 4195 in combination with either 10 or W2).

Correlation of ELISA values and end point titers. In addition to the human immune and normal human serum reference serum standards, eight serum samples were selected at random and assayed to determine the relationship between ELISA optical density value and end point titer. The reciprocal of the lowest serum dilution giving an ELISA value ≥0.100 A400 unit was considered the end point titer. The optical density value obtained at the 1 : 128 dilution was chosen for the standard ELISA value. The regression line, slope 1.624, was obtained for IgG (Fig. 5). Regression lines obtained for IgM and IgA gave slopes of 3.416 and 5.628, respectively. On the basis of these regression lines, a difference in optical density values between acute and convalescent sera was deemed significant if it was ≥0.2 (IgG) or 0.1 (IgM, IgA).

Detection of class-specific antibody changes in postpartum fever patients. Acute and convalescent phase sera from 10 women with postpartum fever of mycoplasmal origin were tested for IgG, IgM, and IgA antibody. The differences between acute and convalescent levels are shown in Fig. 6. On the basis of the values established in the regression analysis, six of the 10 patients demonstrated a significant increase in one or

more antibody classes. Of these, one patient had a significant rise in all three antibody classes; four patients studied had concomitant rises in both IgG and IgM; and one had an increase in IgM. Of the remaining four patients, one had stable high levels of IgG and IgM; two had significant decreases in IgG and IgM, and the last had a significant decrease in IgG.

Comment

The antigenic determinant of *M. hominis* as well as the association of specific antigens with disease is relatively unknown.[11] Until the identification, purification, and characterization of these antigens with respect to their immunogenicity in humans is pursued, it is unlikely that a suitable purified antigen preparation will be available. When a mixed antigen preparation is used, primary considerations are the adsorption characteristics of the carrier surface and the competition among proteins for binding sites.[12] Serial dilutions of positive sera give shallow slopes with inadequate coating and adsorption of mixed antigen preparation.[12] With the *M. hominis* ELISA cell lysate antigen, the slopes observed for serial dilution of positive sera (Figs. 2 to 4) were steep whereas those of negative sera were shallow, indicating that use of a mixed antigen preparation was not a problem.[12]

The ubiquity of genital mycoplasmas coupled with the commensal nature of other mycoplasma species in the oral cavity of humans makes the determination of assay specificity difficult at best. Human sera with antibody to *M. pneumoniae* did not react with *M. hominis* antigen. No cross-reactions were observed between *M. hominis* and other mycoplasmas of human origin in the rabbit system.[11] However, a one-way cross-reaction between rabbit antisera to *U. urealyticum* and *M. hominis* antigens has been previously reported.[11] No significant correlation occurred between levels of antibody detected to *M. hominis* and *U. urealyticum* in 207 individuals. More important, individuals with significant changes in antibody levels to one antigen did not demonstrate changes to the other antigen, even in the antibody class (IgM) with the greatest degree of correlation. In a previous study,[8] individuals with antibody to one microorganism were seronegative to the other, thus suggesting that the antibody response is specific. The correlation of the *M. hominis* ELISA results with the mycoplasmacidal test as well as the ureaplasma ELISA with the metabolism inhibition test[8] is additional evidence for the validity of the assay. However, the potential for limited cross-reactions should always be considered, particularly with respect to IgM, in interpretation of data.

The observed discrepancies between cultural status and presence of antibody are predictable. A percentage

of culturally negative, serologically positive individuals is not uncommon[13]; whether this represents failure in culture technique, previous clearance of the organism, or nonspecificity is not known. Culturally negative individuals were most frequently positive in the IgG class, suggesting that these individuals may have had previous exposure to and subsequent clearance of *M. hominis*. It is of interest that 19 of the 48 IgG-positive, culturally negative individuals had evidence of tubal disease, suggesting that a previous infection with *M. hominis* may have occurred. The relatively low numbers of culturally negative individuals with specific IgA or IgM antibody (Table II) would also support a theory of clearance of the microorganism.

A significant association of antibody to *M. hominis* with infection has been shown in acute pyelonephritis,[3] postpartum fever,[7] and salpingitis.[14] In these instances, significant changes in titer correlated with both disease symptoms and cultural isolation. In the postpartum fever patients in the present study, significant changes were found in IgM (80%) and IgG (70%) levels, which is consistent with an active infection. In a recent study of acute pelvic inflammatory disease,[15] significant changes in antibody levels to *M. hominis* were observed in only 23% (IgG), 12% (IgA), and 10% (IgM) of patients. However, the cultural status of these individuals was not determined with respect to *M. hominis*, and other infectious agents including *Chlamydia trachomatis* and *Neisseria gonorhoeae* were isolated from 50% of the patients. It is possible that *M. hominis* was a causative agent in only a small percent of individuals with acute pelvic inflammatory disease, thus explaining the low incidence of significant changes in antibody levels, particularly in the IgM class.

The presence of IgM and IgA antibodies as well as IgG antibodies in healthy women (Table II) suggests that determination of class-specific antibody in a single serum sample may not necessarily be of diagnostic value. In addition, the seroconversion of women during normal pregnancies[4] suggests that interpretation of results obtained with acute and convalescent sera should be made in conjunction with clinical manifestations and cultural isolation. In a recent study of pregnant women,[16] the ELISA did not detect significant changes in antibody levels between acute and convalescent sera in asymptomatic patients but did detect significant changes in antibody levels in women with clinical amnionitis and in women in whom *M. hominis* was isolated from amniotic fluid.

Differences observed in the mycoplasmacidal test and ELISA may reflect either an increased sensitivity in the ELISA or a difference in the type of antibody detected. The mycoplasmacidal test detects only antibody that is biologically functional in the assay, whereas ELISA detects all class-specific antibody capable of forming immune complexes with the ELISA antigen. Failure of the ELISA to detect significant strain differences may be attributed to the type of antigen used. Soluble antigens of *M. hominis* are similar whereas differences exist in membrane protein antigens. The ELISA antigen contained both cytoplasmic and membrane antigens; thus dissimilarity due to the latter probably would not have been evident. Furthermore, strain specificity of the mycoplasmacidal test is affected by antigen concentration with loss of individual strain specificity at lower concentrations,[3] and the ELISA antigen contained only 10 μg of protein per milliliter.

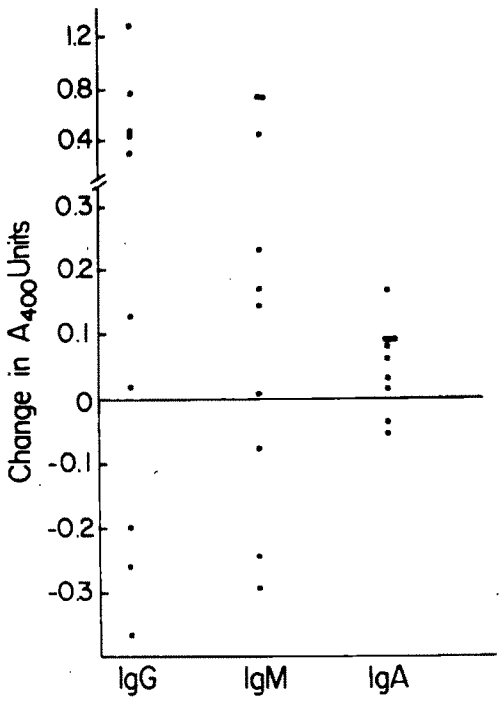

Fig. 6. Differences between acute and convalescent antibody in patients with postpartum fever. All differences represent convalescent value minus acute value for each patient.

The assays currently used to determine the presence of antibody require careful regulation of mycoplasma cell numbers and multiple strains of *M. hominis*. Few clinical laboratories possess the facilities or expertise to perform such assays. ELISA technology, however, has been readily adapted by commercial sources for routine use in the clinical setting. The ELISA presented in this study for detection of antibody to *M. hominis* is sensitive and correlates well with the mycoplasmacidal test. However, it is obvious that the ELISA, like other serologic assays, will require the use of antigen pools that reflect strain heterogeneity for optimal antibody detection. Our results suggest that type strain PG21 in combination with one or two other strains would be optimal for antibody detection. The optimal choice of strain combination may vary with the incidence of isolation within a given population, and this variable should be

considered when the assay is established. The sensitivity and simplicity of the ELISA in conjunction with its ability to detect class-specific antibody changes make this assay a potentially useful tool in both the clinical and research settings for evaluating the etiologic significance of *M. hominis* in disease.

We thank Dr. Edwin Bradley for help with statistical analysis of the data and Drs. J. G. Tully and J. W. Simecka for critical review of the manuscript.

Fetal biophysical profile scoring: Selective use of the nonstress test

F. A. Manning, M.D., I. Morrison, M.B., I. R. Lange, M.B., C. R. Harman, M.D., and P. F. C. Chamberlain, M.D.

Winnipeg, Manitoba, Canada

The fetal biophysical profile score was modified by selective use of the nonstress test. In 2712 study patients (7851 tests) the incidence of nonstress test was reduced to 2.7% with no measurable effect or test accuracy. The nonstress test was most useful in evaluation of abnormal ultrasound monitored variables. (AM J OBSTET GYNECOL 1987;156:709-12.)

Key words: Fetus, biophysical profile score, dynamic ultrasound scan, nonstress test

The fetal biophysical profile score is reported as a reliable accurate method for antepartum fetal risk assessment.[1] This testing method is usually done in two sequenced steps: an initial dynamic ultrasound scan to record the presence or absence of fetal tone, gross body movements, and fetal breathing and a semiquantitative assessment of amniotic fluid volume followed by a nonstress test.[2] In a prospective blind clinical study in which perinatal morbidity and mortality were used as end points to judge specificity, sensitivity, predictive accuracy, measurement of fetal tone, gross body movement, fetal breathing movement, and amniotic fluid volume when compared to the nonstress test yielded superior results.[2] In a prospective randomized clinical trial comparing the nonstress test to the fetal biophysical profile score Platt et al.[3] reported a significant improvement in positive predictive value of abnormal outcome with fetal biophysical profile scoring and a better but nonsignificant improvement in negative predictive accuracy, sensitivity, and specificity.[3] The advantage, if any, of performing a nonstress test when the dynamic ultrasound-monitored variables of the fetal biophysical profile score are normal is unknown and forms the basis of this report. The purpose of this study was twofold: to determine the distribution of nonstress test results after initial dynamic ultrasound variable monitoring and to determine perinatal outcome, as reflected by perinatal mortality, achieved by primary dynamic ultrasound variable monitoring and selective use of the nonstress test.

Total patients	2712	100
Total fetuses	2758	100

Method

The study population consisted of 2712 consecutive high-risk patients referred for antepartum fetal risk evaluation by fetal biophysical profile scoring; in total 2758 fetuses were studied (46 twin pregnancies). The indications for initial referrals are listed in Table I; the mean fetal age at referral was 36.4 ± 1.4 weeks (range, 26 to 44 weeks).

In each patient at each visit a dynamic ultrasound scan was done to record the presence or absence of fetal tone, gross body movements, and fetal breathing movements and to assess amniotic fluid volume; these variables were coded as normal or abnormal according to fixed criteria (Table II). If these initial variables were all normal, a nonstress test was not done unless specif-

Table II. Technique and interpretation of biophysical profile scoring

Biophysical variable	*Normal (score = 2)*	*Abnormal (score = 0)*
Fetal breathing movements	One or more episodes of ≥30 sec in 30 min	Absent or no episcde of ≥30 sec in 30 min
Gross body movements	Three or more discrete body/limb movements in 30 min (episodes of active continuous movement considered as single movement)	Two or less episodes of body/limb movements in 30 min
Fetal tone	One or more episodes of active extension with return to flexion of fetal limb(s) or trunk; opening and closing of hand considered normal tone	Either slow extension with return to partial flexion or movement of limb in full extension or absent fetal movement
Reactive fetal heart rate	Two or more episodes of acceleration of ≥15 bpm and of ≥15 sec associated with fetal movement in 20 min	Less than 2 episodes of acceleration of fetal heart rate or acceleration of <15 bpm in 40 min
Qualitative amniotic fluid	One or more pockets of fluid measuring ≥1 cm in two perpendicular planes	Either no pockets or a pocket <1 cm in two perpendicular planes

Table III. Distribution of test score results and comparison with nonstress test results

ically requested. If one or more of the dynamic ultrasound variables were abnormal, a nonstress test was always done and interpreted according to fixed criteria (Table II). Repeated testing was recommended on a twice weekly basis in postdate pregnancies (>42 completed weeks) and diabetes (gestational and insulin-dependent) and on a weekly basis in all other high-risk groups. Criteria for intervention for test results were fixed. If the total score was 4 or less, intervention for fetal indication was always undertaken. A score of 6 was considered as indication for induction in the mature fetus (>36 weeks) and an indication for repeat testing in the immature fetus (<36 weeks); with a persistent score of 6 intervention was always undertaken. Oligohydramnios was always considered an indication for intervention regardless of the presence or absence of the other score variables, provided the membranes were intact and the fetal genitourinary system was judged as normal.

Perinatal mortality, both gross and corrected, was used to judge perinatal outcome and test accuracy. A corrected perinatal death was defined as death of a structurally normal nonisoimmunized fetus with a birth weight of at least 500 gm until and including the twenty-eighth day of neonatal life.

Results

A total of 7851 dynamic ultrasound tests were done in the 2712 study patients (mean, 2.9 tests per patient; range, one to 16 tests per patient). The four dynamic ultrasound-monitored variables were normal in 7663 of 7851 tests (97.60%). In 153 tests (1.94%) a single ultrasound variable was abnormal, in 16 tests two variables were abnormal (0.22%), in 15 tests three variables were abnormal (0.19%), and in four tests all variables were abnormal (0.05%). The frequency of abnormality of each variable is listed in Table III. In decending order of frequency abnormal tests were absent fetal breathing (149 tests), absent fetal tone (39 tests), abnormal amniotic fluid volume (38 tests), and abnormal fetal movements (20 tests).

A nonstress test was performed as an additional test

in 212 of the 7851 tests (2.7%). In 34 instances a nonstress test was done by physician request despite all four ultrasound-monitored variables being normal; all 34 tests were reactive (100%). In 178 instances a nonstress test was done because one or more ultrasound-monitored variables were abnormal (2.26% of total tests). The incidence of an abnormal nonstress test result increased progressively as the number of abnormal ultrasound-monitored variables increased, ranging from 35.6% nonreactive tests with one abnormal ultrasound variable to 100% nonreactive tests when three or more ultrasound-monitored variables were abnormal (Fig. 1).

Seventeen perinatal deaths occurred among the 2752 fetuses studied (gross perinatal mortality, 6.17 per 1000), of which 10 were stillbirths (gross stillbirth rate, 3.63 per 1000). Thirteen of the 17 perinatal deaths were due to either major structural anomaly (10 deaths) or severe isoimmunization and fetal hydrops (three deaths). The corrected perinatal mortality in this study population was 1.45 per 1000 (four deaths). In two of these corrected perinatal deaths fetal death occurred within 1 week of a normal test result, yielding a false negative rate of 0.73 per 1000; in one instance the death resulted from massive abruptio placentae and in the other the cause of death was undetermined and presumed asphyxial in origin. The remaining two corrected deaths occurred despite intervention for an abnormal score and are also presumed to be asphyxial in origin.

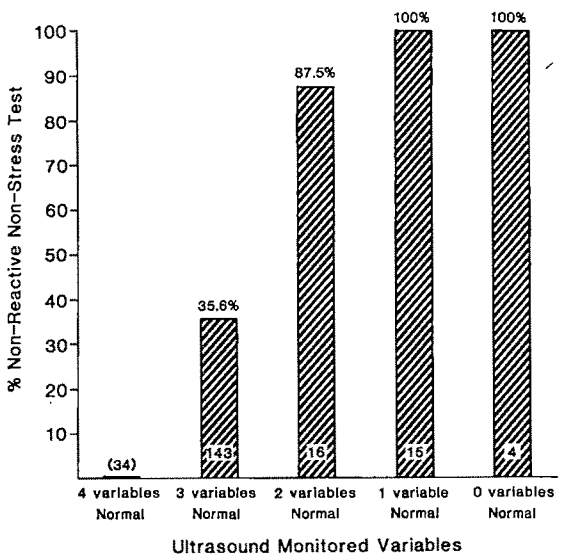

Fig. 1. Histogram of distribution of nonreactive nonstress test results as compared to the results of the dynamic ultrasound-monitored variables. A detailed breakdown of individual variable results to the nonstress test results is given in Table III.

Comment

Before accepting a change in a testing method it is essential to demonstrate that the proposed modification yields similar or superior test accuracy and is of some clinical advantage. The modification of the fetal biophysical profile score by selective use of the nonstress test component as described here appears to satisfy these criteria. The modified testing method yielded a gross perinatal mortality of 6.17 per 1000, a corrected perinatal mortality of 1.43 per 1000, and a false negative rate of 0.73 per 1000. In a large prospective clinical study using the complete fetal biophysical score, the comparable rates were a gross perinatal mortality of 7.37 per 1000, a corrected perinatal mortality of 1.90 per 1000, and a false negative rate of 0.65 per 1000.[1] Other studies using the complete fetal biophysical profile score have reported similar results.[4-6] Therefore the modification studied, that is, selective use of the nonstress test, has not produced any measurable decrease in test accuracy.

The main clinical advantage of this modification is the elimination of the need for performing the nonstress test in all but 2.7% of patients, thereby reducing testing time and fetal exposure to additional Doppler ultrasound energy. The time required to perform the dynamic ultrasound monitoring in this study was not recorded, but in previous studies it is reported that in 97% of instances these variables when normal will be observed within the first 10 minutes.[1] Since in this study, as in previous studies, the large majority of dynamic ultrasound tests will yield normal variables (97.73%), testing time is short and patients may be assessed more rapidly. In this center the modification has dramatically improved the efficacy of the testing unit, shortened the duration of the patient's visit, and increased the number of tests that may be performed daily. This advance is achieved without any measurable change in predictive accuracy.

The relationship between the ultrasound-monitored variables and the nonstress test results is intriguing. The acute fetal biophysical variables measured, fetal breathing, tone, movement, and heart rate acceleration with movement, are known to be influenced by fetal sleep-wake cycles.[7] In the small number of cases studied when all ultrasound-monitored variables were normal, the nonstress test was always reactive (34 cases); whether this association is invariable cannot be determined from this sample size. This association suggests that when testing occurs during a time when the normal fetus is in active sleep, all acute variables are likely to be normal. In contrast, when any single ultrasound-monitored variable other than amniotic fluid volume, is abnormal, the addition of the nonstress test is useful in differentiating the fetus in quiet sleep from the compromised fetus. In this study absent fetal breathing movements were the most common single abnormal variable. Fetal breathing movements are known to be periodic in nature and markedly influenced by sleep state.[8] When fetal breathing movements were absent

for 30 minutes, an immediate nonstress test yielded normal results in 65% of cases (80 of 123 tests). This relatively high frequency of a reactive nonstress test in such cases is probably the result of the extended testing time with spontaneous fetal transition from quiet to active sleep. Since the predictive accuracy of the nonstress test and fetal breathing movements when considered as single variables is equal, the presence of a reactive nonstress test despite absent fetal breathing movements may be considered reassuring.[9] A similar effect of sleep state may explain the high probability of a reactive nonstress test despite either abnormal fetal movements or tone and again is considered reassuring. Decreased amniotic fluid volume shows a distinctly different association with the nonstress test results, in this small sample size (n = 38) yielding a nonreactive test in 33 instances (86.9%). Since decreased amniotic fluid volume is not acutely influenced by fetal sleep state and is associated with a sharp increase in perinatal compromise and mortality,[10, 11] this high correlation is not unexpected. When two or more ultrasound-monitored variables were abnormal, the probability of a nonreactive nonstress test result rose dramatically. Since the risk of perinatal compromise rises as more ultrasound-monitored variables become abnormal,[2] this association is more likely due to intrauterine asphyxia and less likely due to influence of fetal sleep state.

In theory the fetal biophysical profile score measures immediate fetal condition as reflected by the presence of central nervous system–regulated acute biophysical variables (movement, breathing, tone, and heart rate reactivity) and chronic fetal condition as reflected by amniotic fluid volume. As demonstrated in this study and others,[2, 4-6] the predictive value of these acute variables are interchangeable and no advantage is gained provided all or most are normal. In contrast, amniotic fluid volume determination is a separate and critical variable improving predictive accuracy in both the general high-risk groups and specific high-risk subsets such as the postmature fetus[12] and the fetus with intrauterine growth retardation.[13] We are of the opinion then that any method of risk assessment using acute variables, be they the nonstress test alone or dynamic ultrasound-monitored variables such as fetal breathing, movement, and tone, also requires consideration of amniotic fluid volume to achieve maximal predictive accuracy. If this principle were accepted, then at least two testing strategies would arise. One approach would be to record the nonstress test and then use B-mode ultrasound to assess amniotic fluid volume. To date the results of clinical testing of this method are not reported. This present study presents the alternative approach, that is, combining simultaneous amniotic fluid volume and fetal breathing, movement, and tone as the primary test, reserving the nonstress test for cases in which one or more of these variables are abnormal. This approach yielded improvement in testing logistics without compromising accuracy. Whether this approach is better than the alternate nonstress test and amniotic fluid volume determination cannot be determined but warrants further investigation.

Embryonic trunk circumference: A new biometric parameter for estimation of gestational age

E. Albert Reece, M.D., Angela L. Scioscia, M.D., Jacqueline Green, M.S., R.D.M.S., Theresa Z. O'Connor, M.P.H., and John C. Hobbins, M.D.

New Haven, Connecticut

One hundred thirty-one uncomplicated, singleton pregnancies between 7 and 12 weeks of gestation were ultrasonically examined. Evaluation included confirmation of cardiac activity and measurements of fetal crown-rump length and trunk circumference. Both crown-rump length and trunk circumference were curvilinearly correlated with gestational age. A second- and third-degree polynomial equation best described this curvilinear relationship between trunk circumference and gestational age and between crown-rump length and gestational age. The crown-rump length and trunk circumference were similar in their prediction of gestational age, but the combination of the two parameters did not improve the prediction of gestational age. A nomogram of gestational age as predicted by trunk circumference was generated. These data provide an additional measurement for the estimation of gestational age in the first trimester of pregnancy. (AM J OBSTET GYNECOL 1987;156:713-5.)

Key words: Ultrasound, abdominal circumference, embryonic age, gestational age

In 1973 Robinson[1] described the ultrasonic measurement of the fetal crown-rump length and its correlation with gestational age. Subsequent reports have shown that a crown-rump measurement during the first trimester is predictive of gestational age within 4.7 days. The original study was performed on B-mode scanners and was subsequently confirmed with real-time sonography.[2-5] When measured properly the crown-rump length can estimate the gestational age with a high degree of accuracy. However, it is the only measurement with which to estimate gestational age in the first trimester. Additional measurements for the corroboration of age are currently unavailable.

The purpose of this study was to determine whether an additional biometric parameter could be generated for estimating the embryonic age that would serve as a useful adjunct in corroborating or rejecting the prediction of age obtained by the crown-rump length.

Patients and methods

Patients with uncomplicated pregnancies were recruited from the private and university practices for ultrasound examinations. Patients were included in this study if they had regular menses, if the date of the last menstrual period was known, and if the gestational age was confirmed by embryonic crown-rump length measurement (within 4 days of each other). All pregnancies were singleton gestations. The examinations were conducted with a 5.0 MHz sector scanner or Technicare Aloka 280 SL (General Electric RT 3000, Milwaukee, Wisconsin) with dynamic focusing capability in which optimal resolution was possible at varying depths of tissue penetration. Each examination included a measurement of crown-rump length and trunk circumference. The crown-rump length was measured in the longest axis of the fetus, excluding limbs, in the manner described by Robinson and Fleming.[1, 5] The trunk circumference was measured perpendicular to the long axis at a point just caudal to the cardiac pulsation (Fig. 1). The trunk circumference was calculated as the mean of two trunk diameters multiplied by 3.14. The data, which comprised a single examination from each patient, were analyzed by producing scatter plots, then determining the polynomial equation that best described the relationship between crown-rump length and trunk circumference and gestational age as calculated by the last menstrual period. In addition, a multiple regression analysis was used to determine whether the combination of trunk circumference and crown-rump length would predict gestational age more precisely than crown-rump length alone.

Results

One hundred thirty-one uncomplicated pregnancies between 7 and 12 weeks of gestation were examined, with low interobserver error. The trunk circumference

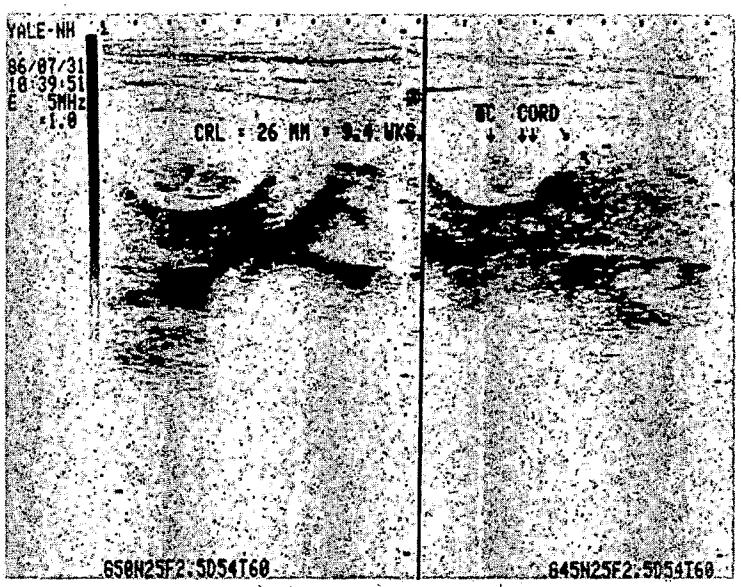

Fig. 1. Ultrasound picture of a first-trimester conceptus, with the embryo seen in longitudinal view and its crown-rump length *(CRL)* measured. Note also the cross-sectional *(TC)* view of the embryo taken below the cardiac pulsation. The umbilical cord *(CORD)* can be seen (⇊) as it enters the fetal abdomen and also as it inserts itself into the placenta (⇵).

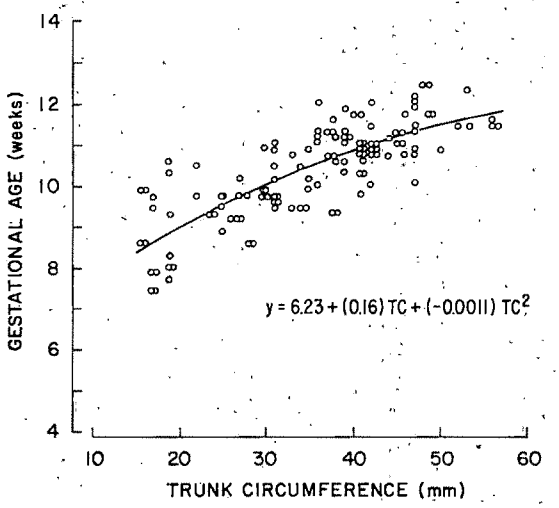

Fig. 2. Scattergram of trunk circumference measurements (X axis) predicting gestational age (Y axis), with fitted second-degree polynomial regression line.

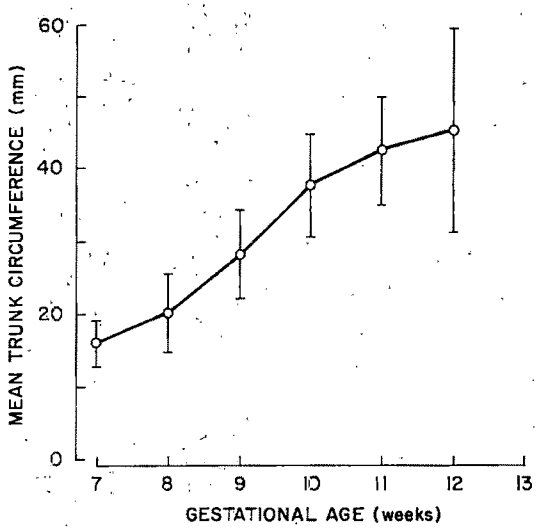

Fig. 3. Mean trunk circumference measurements ± 2 standard deviations plotted against gestational age.

was highly correlated with gestational age and with the crown-rump length ($p < 0.0001$). The growth of trunk circumference over time as a measure of gestational age was curvilinear and was best represented by a second-degree polynomial equation (Figs. 2 and 3). Growth of the crown-rump length with age and with trunk circumference was also curvilinear and best described by a third-degree polynomial equation (Fig. 4). Tests of higher degree terms showed them to be nonsignificant. The equations describing the above relationships are:

$$GA = 6.23 + (0.16)TC + (-0.0011)TC^2;\ R^2 = 0.58$$

$$GA = 5.23 + (2.53)CRL + (-0.345)CRL^2 + (0.0172)CRL^3;\ R^2 = 0.71$$

A nomogram of gestational age as predicted by the trunk circumference was generated (Table I). Multiple regression analysis revealed that the combination of trunk circumference and crown-rump length did not improve the prediction of gestational age over that using crown-rump length alone.

Comment

Embryonic growth observed by measuring the long axis of the fetus or the crown-rump length follows a curvilinear growth pattern over time and predicts gestational age in the first trimester of pregnancy with an accuracy of ±4.7 days.[2] Chervenak et al.,[6] using basal body temperature to date conception, have shown the crown-rump length to be a more accurate measure of gestational age than the human chorionic gonadotropin titer done during the first trimester. Until now, the crown-rump length measurement has been the most accessible and accurate predictor of gestational age and the only available method for estimating gestational age in the first trimester. The current study has demonstrated that the growth of the embryonic trunk circumference is similar to that of the crown-rump length and provides an additional means of estimating gestational age in the first trimester with an accuracy of ±3 days.

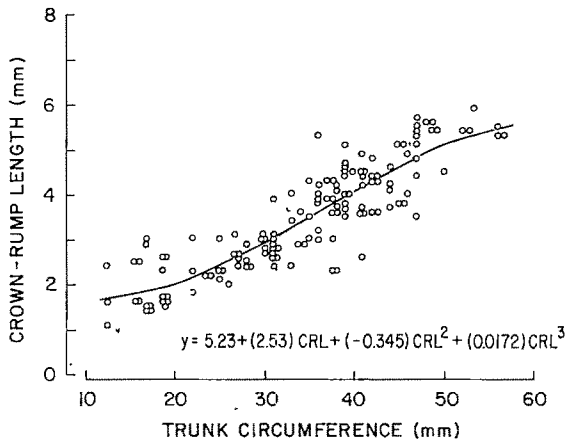

Fig. 4. Scattergram of crown-rump length plotted against trunk circumference, with fitted third-degree polynomial regression line.

The adjunctive utilization of trunk circumference measurements to estimate age may serve to confirm or reject information derived from crown-rump length determinations.

Levels of epidermal growth factor binding in third-trimester and term human placentas: Elevated binding in term placentas of male fetuses

Melinda J. Brown, Ph.D., Christine L. Cook, M.D., John L. Henry, M.S., and Gregory S. Schultz, Ph.D.
Louisville, Kentucky

Specific binding of iodine 125–labeled epidermal growth factor was measured in membrane homogenates of third-trimester and term human placentas of male and female fetuses. All placentas ($n = 35$) generated curvilinear Scatchard plots, and all placentas had similar equilibrium dissociation constants for both high-affinity (210 pmol/L) and low-affinity (830 pmol/L) binding sites. Mean maximum number of available binding sites of term placentas from male fetuses (330 ± 110 fmol/mg protein; $n = 11$) was significantly higher ($p < 0.001$) than that of female fetuses (170 ± 80 fmol/mg protein, $n = 13$). Occupation of epidermal growth factor receptors by endogenous epidermal growth factor could not account for the difference in levels of epidermal growth factor binding. Kendall's rank order correlation test demonstrated a significant positive correlation of the gestational age in weeks with the maximum number of epidermal growth factor receptors in placentas from male fetuses ($p < 0.002$; $T = 0.527$; $n = 17$) and female fetuses ($p < 0.01$; $T = 0.404$; $n = 18$). These results indicate (1) that there is a sexual dimorphism in the level of epidermal growth factor receptors in placentas of male and female fetuses during the third trimester and (2) that the level of epidermal growth factor receptors increases during the third trimester for placentas of both male and female fetuses. (Am J Obstet Gynecol 1987;156:716-20.)

Key words: Epidermal growth factor binding, placenta, development

The presence of high levels of epidermal growth factor binding in placental tissue[1] strongly suggests that epidermal growth factor plays important physiologic roles in fetoplacental function. For example, epidermal growth factor has been shown to stimulate the secretion of human chorionic gonadotropin and human placental lactogen in cultures of normal term human placental cells[2] and to stimulate the secretion of human chorionic gonadotropin[3, 4] and progesterone[5] in cultured human choriocarcinoma cells. All of these biologic actions of epidermal growth factor are presumably mediated by receptors for epidermal growth factor, and thus the response of tissues to epidermal growth factor may be regulated in part by their levels of epidermal growth factor receptor. Regulation of epidermal growth factor receptor levels in the placenta is not well understood. We have measured levels of epidermal growth factor binding in placental membranes to determine whether receptor levels change during development in the third trimester and whether differences exist between male and female placental tissue at term.

Material and methods

Common chemicals, chloramine T, and testosterone, were obtained from Sigma Chemical Co., St. Louis, Missouri. Sodium iodide I-125 solution was obtained from Amersham Corp., Arlington Heights, Illinois. Gelman filters were obtained from Gelman Instruments, Quincy, Massachusetts.

Tissue collection and preparation. Preterm and term human placentas were obtained after normal vaginal delivery or after cesarean section. All placentas were immediately placed on ice, brought to the laboratory, and frozen. Placentas were homogenized with a Polytron homogenizer (Brinkman Instruments, Westbury, New Jersey) at 4° C in buffer (10 mmol/L Tris hydrochloride [pH 7.0], 250 mmol/L sucrose, and 1 mmol/L calcium chloride), then filtered through cheesecloth as previously described.[6] Homogenates were stored in aliquots at −20° C until assayed for binding. Protein content in each homogenate was determined after membranes were digested at 80° C in 0.1 mol/L sodium hydroxide containing 0.1% sodium dodecyl sulfate by the method of Lowry et al.,[7] with bovine serum albumin used as the standard.

Isolation and iodination of mouse epidermal growth factor. Mouse epidermal growth factor was isolated and purified to homogeneity from the submandibular glands of testosterone-stimulated male mice according

to the procedure of Savage and Cohen.[8] Mouse epidermal growth factor was iodinated with chloramine T, and concentrations of mouse epidermal growth factor solutions were determined by spectrophotometric absorption at 280 nm (1 mg/ml = 3.09 absorption units).

Epidermal growth factor binding studies. Specific epidermal growth factor binding was measured as described previously.[6] Briefly, in experiment 1, aliquots (100 μl) of homogenate containing 50 μg of protein were incubated for 2 hours at 22° C with increasing concentrations of iodine 125–labeled mouse epidermal growth factor (9 to 5100 pmol/L; specific activity, 226 μCi/μg) in the presence and absence of 0.2 μmol/L unlabeled epidermal growth factor. Total volume of the incubation mixture was brought to 200 μl by addition of buffer (150 mmol/L sodium chloride and 1.0% bovine serum albumin). After incubation was complete suspensions were collected by filtration on 0.2 μm Gelman filters (GA-8), washed with 10 ml of ice-cold buffer (10 mmol/L Tris hydrochloride, pH 7.0), and counted in a Searle Model 1119 autocounter (Searle Laboratories, Chicago, Illinois) with a counting efficiency of 63% for ^{125}I. Alternatively, in experiment 2, after the material was incubated as above with increasing concentrations of ^{125}I-labeled epidermal growth factor (5 to 5000 pmol/L; specific activity, 343 μCi/μg), 3 ml of cold buffer was added to membrane suspensions, and suspensions were then centrifuged at 10,000 × g for 20 minutes at 4° C. Supernatant solutions were poured off, and pellets were counted in a Beckman 4000 Biogamma counter (Beckman Instruments Inc., Fullerton, California) with an efficiency of 70% for ^{125}I. We have demonstrated previously that binding of ^{125}I-labeled epidermal growth factor to human placental membrane reaches equilibrium after 2 hours at 22° C and that binding of ^{125}I-labeled epidermal growth factor is highly specific with these techniques.[9]

Specific binding data were calculated by subtracting the amount of epidermal growth factor bound in the presence of unlabeled mouse epidermal growth factor from that bound in the absence of unlabeled mouse epidermal growth factor. Specific binding was transformed by the method of Scatchard, and equilibrium dissociation constants for high- and low-affinity sites and maximum number of available binding sites were determined by use of the ISIS-12 computer program (National Institutes of Health, Bethesda, Maryland).[10] This program estimated affinities and binding capacities of two heterogeneous binding sites by the limiting slope technique. Identity of the sex of the fetus was masked until data for placental homogenates were calculated.

Rapid debinding of endogenous epidermal growth factor and rebinding of ^{125}I-labeled epidermal growth factor. Incubation of ^{125}I-labeled epidermal growth factor with placental membrane homogenates under the conditions described above measures unoccupied epidermal growth factor receptors. To measure the percent of epidermal growth factor receptors occupied by endogenous epidermal growth factor, membranes were stripped of bound epidermal growth factor by brief exposure to low pH at cold temperature as described previously.[11] Specific epidermal growth factor binding was then measured and compared with the level of epidermal growth factor binding in companion membranes not exposed to debinding conditions. Briefly, membranes were exposed to 40 mmol/L sodium acetate, pH 4.5, at 4° C for 4 minutes, then centrifuged at 10,000 × g for 2 minutes at 4° C with a Beckman microfuge. The supernatant solution was removed, and membranes were immediately resuspended in 40 mmol/L sodium acetate, pH 7.0. Specific binding was then measured as described above. This procedure removed >90% of ^{125}I-labeled epidermal growth factor bound to hepatocytes in culture membranes, with <10% loss of epidermal growth factor rebinding capacity in vitro.[11]

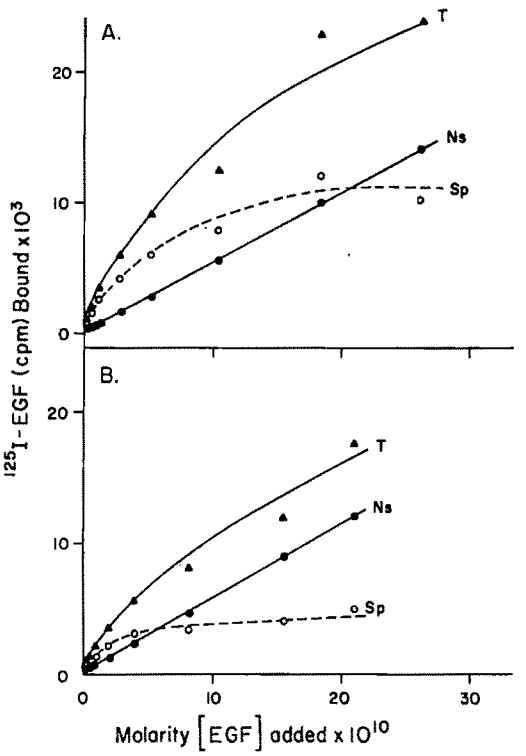

Fig. 1. Titration of ^{125}I-labeled epidermal growth factor binding to homogenates of normal term placentas. Aliquots of placental homogenate containing 50 μg of protein were incubated with increasing concentrations of ^{125}I-labeled mouse epidermal growth factor in the presence or absence of 0.2 μmol/L unlabeled epidermal growth factor for 2 hours at 22° C. Specific binding (○) was calculated by subtracting nonspecific binding (●) from total binding (▲). *A*, Epidermal growth factor binding to placenta of male fetus. *B*, Epidermal growth factor binding to placenta of female fetus.

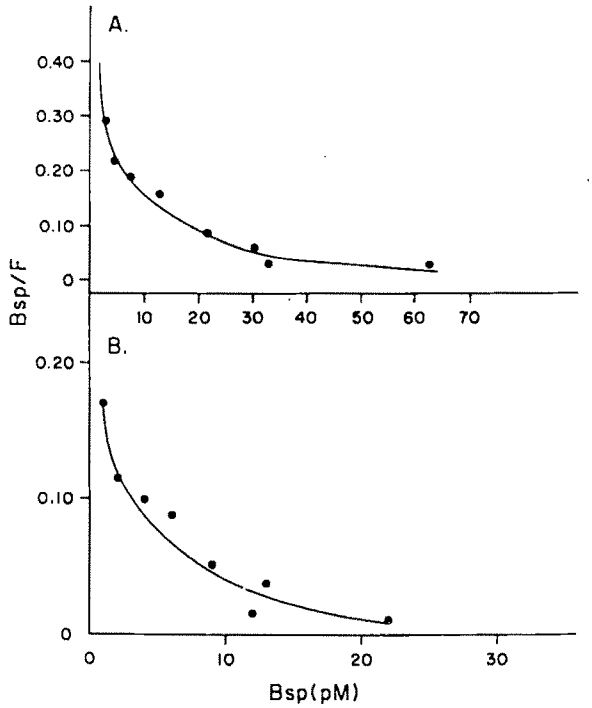

Fig. 2. Scatchard plots of specific ^{125}I-labeled epidermal growth factor binding from Fig. 1. Equilibrium dissociation constants and the maximum number of available binding sites were determined by the ISIS-12 program. *A*, Term placenta of male fetus. *B*, Term placenta of female fetus.

Statistical analysis. Kendall's rank order correlation test and Student's *t* test were used for statistical analysis of the data.

Results

Specific binding to term placentas. Representative titration curves of specific binding of ^{125}I-labeled epidermal growth factor to crude membranes from term placentas of male and female fetuses are shown in Fig. 1. Nonspecific binding was linear for placentas from both male and female fetuses (mean $R^2 = 0.99$; $n = 24$) over the range of ^{125}I-labeled epidermal growth factor added and represented approximately 60% of total binding at high levels of ^{125}I-labeled epidermal growth factor. Specific binding approached a plateau at approximately 1 nmol/L, indicating saturation of specific binding sites in homogenates of 20 of 25 term placentas. The five placental homogenates not approaching saturation were all from male fetuses. The average half-saturation concentration of ^{125}I-labeled epidermal growth factor estimated from titration curves was 710 ± 90 pmol/L and agreed well with the average low-affinity dissociation constant calculated from Scatchard plots.

Scatchard transformation of specific binding generated curvilinear plots in all term placentas (Fig. 2). Similar equilibrium dissociation constants were derived in all male (n = 11) and all female placentas (n = 13) for low-affinity binding sites (dissociation constant = 720 ± 180 pmol/L) and for high-affinity binding sites (dissociation constant = 140 ± 60 pmol/L).

The average of the maximum available binding sites extrapolated from Scatchard plots from experiment 1 of term placentas from six male fetuses was significantly higher ($p < 0.005$ by *t* test) than the average of the maximum binding sites of term placentas from eight female fetuses (β_{max} = 310 ± 40 and 130 ± 20 fmol/mg protein, respectively). In experiment 2, additional placentas from five male and five female fetuses were assayed for specific epidermal growth factor binding. As found in experiment 1, Scatchard transformation of specific epidermal growth factor binding indicated that placental membranes from male fetuses bound significantly ($p < 0.05$ by *t* test) more epidermal growth factor than placental membranes from female fetuses (360 ± 90 fmol/mg of protein for male and 230 ± 70 fmol/mg of protein for female fetuses). When data from the two experiments are combined, placentas from 11 male fetuses bound significantly ($p < 0.001$ by *t* test) more epidermal growth factor than placentas from 13 female fetuses (330 ± 100 versus 170 ± 80 fmol/mg of protein).

It is interesting to note that when specific epidermal growth factor binding was calculated by use of values obtained at a near-saturating concentration (1 nmol/L) of ^{125}I-labeled epidermal growth factor from data collected in experiment 2, the average level of binding in male fetuses (100 ± 40 fmol/mg of protein) was higher than the average level of binding in female fetuses (90 ± 30 fmol/mg of protein); however, the difference did not reach statistical significance ($p < 0.5$). Thus it is important to analyze placental binding by conducting multipoint titration analysis with high levels of epidermal growth factor and to analyze specific binding by Scatchard transformation.

When placental membranes from four male and four female term fetuses were incubated with ^{125}I-labeled epidermal growth factor and washed by centrifugation as described in experiment 2, then subjected to rapid debinding conditions, 85% ± 5% of the specifically bound ^{125}I-labeled epidermal growth factor was removed. Thus endogenous epidermal growth factor bound to receptors of male or female fetuses also should be removed equally well by the rapid debinding conditions. To determine the extent of occupancy of epidermal growth factor receptors by endogenous epidermal growth factor, placental membranes from four male and four female term fetuses were subjected to rapid debinding conditions, assayed for specific epidermal growth factor binding, and then compared with companion samples of placental membranes not subjected to rapid debinding conditions. Recovery of spe-

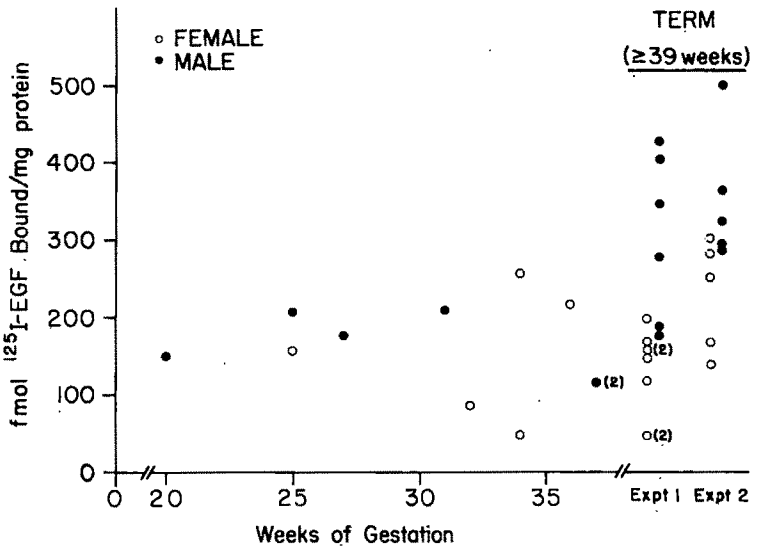

Fig. 3. Correlation between gestational age and level of epidermal growth factor binding in placental homogenates of male and female fetuses. Level of epidermal growth factor binding was determined from the ISIS-12 program after Scatchard transformation of binding data and was significantly correlated with fetal age in weeks of gestation when subjected to Kendall's rank correlation test.

cific epidermal growth factor binding after rapid debinding and rebinding was very similar in placental membranes from male and female fetuses (92% ± 17% and 90% ± 13%, respectively). Assuming any permanent denaturation of epidermal growth factor receptor during rapid debinding is identical between placental membranes of male or female fetuses, occupation of epidermal growth factor receptors by endogenous epidermal growth factor cannot explain the approximate twofold increases in epidermal growth factor binding observed in placental membranes of male fetuses compared with female fetuses.

Specific binding to preterm placentas. Titration of ^{125}I-labeled epidermal growth factor binding to homogenates of preterm placentas was very similar to that of homogenates obtained from term placentas. Nonspecific binding was linear in the range of the assay (mean $R^2 = 0.99$; $n = 11$) and represented approximately 60% of the total binding at high levels of ^{125}I-labeled epidermal growth factor. Specific binding plateaued in all 11 homogenates, and Scatchard transformations were curvilinear. Dissociation constants for low- and high-affinity sites were 560 ± 100 and 210 ± 100 pmol/L, respectively, and were in good agreement with half-saturation values obtained from titration curves. Dissociation constants were not significantly different ($p > 0.5$) between placentas of preterm male and female fetuses.

Kendall's rank order correlation test (Fig. 3) demonstrated a significant positive correlation of gestational age between 20 and 40 weeks with the level of receptors for epidermal growth factor in placentas from male fetuses ($n = 17$; $p < 0.002$; $T = 0.527$) as well as in placentas of female fetuses ($n = 18$; $p < 0.01$, $T = 0.404$).

Comment

Our results demonstrate that membranes from term placentas of normal male fetuses express significantly higher levels of epidermal growth factor binding than membranes from term placentas of normal female fetuses. This difference could not be explained by higher percent occupancy of epidermal growth factor receptors by endogenous epidermal growth factor in placental membranes from female placentas, since rapid debinding of epidermal growth factor followed by measurement of specific epidermal growth factor binding indicated very similar levels of recovery of epidermal growth factor binding compared to untreated membranes. It is interesting to note that Benveniste and Carson[12] also recently reported that epidermal growth factor binding was significantly higher in liver cell membranes prepared from male rats compared with female rats. Thus two tissues have shown sexual dimorphism of epidermal growth factor binding, that is, rat liver and human placenta. Presumably, the higher level of epidermal growth factor binding in the male placenta represents an important physiologic distinction in the magnitude or sensitivity of response to epidermal growth factor between placental cells of male and female fetuses.

We also observed a significant positive correlation between gestational age and epidermal growth factor binding during the second half of pregnancy (20 weeks

to term) for male and female placentas. Our results are in general agreement with those of Carson et al.[13] who reported that Scatchard analysis of levels of specific epidermal growth factor binding to placental membranes showed a significant positive correlation with advancing gestational age during the first and second trimesters (6 to 21 weeks) and at term. Lai and Guyda[2] also reported a significantly higher level of epidermal growth factor binding to cultures of placental cells established from a term placenta compared with that of placental cell cultures established from a placenta of a fetus of 15 weeks' gestation. Levels of epidermal growth factor binding were not correlated with sex of fetuses in either previous study.[2, 13]

The physiologic significance of the increase in level of epidermal growth factor binding during the first, second, and third trimesters of pregnancy suggested by our data and the data of Carson et al.[13] is not known. However, we have noted a peak of maternal urinary epidermal growth factor level around 20 weeks of gestation, followed by a rise near term (unpublished observation). Fluctuations in placental epidermal growth factor receptor level and maternal-fetal blood levels of epidermal growth factor would seem to suggest an important dynamic role of this factor and its receptor in pregnancy.

Regulation of epidermal growth factor receptor levels in the placenta is poorly understood. Placental epidermal growth factor receptors do undergo the expected acute down-regulation phenomenon observed with other cells when exposed to high levels of epidermal growth factor,[2] but further information regarding regulation of epidermal growth factor receptors in placenta cells is lacking. Regulation of epidermal growth factor receptor level has been studied more thoroughly in hepatocytes. Epidermal growth factor binding in membrane preparations from livers of hypothyroid rats was approximately 35% compared with that in euthyroid control animals, and treatment of hypothyroid animals with a single dose of triiodothyronine restored epidermal growth factor binding to near control levels.[14] Also, while epidermal growth factor exposure acutely induced down-regulation of epidermal growth factor receptors in nontransformed rat liver epithelial cells in vitro, epidermal growth factor also increased epidermal growth factor receptor messenger ribonucleic acid levels by threefold to fivefold, thus counterbalancing the acute down-regulation effect to some extent.[15]

Although the physiologic roles of epidermal growth factor and its receptor in the placenta are not clearly understood, the substantial levels of epidermal growth factor receptors in the placenta strongly imply their importance. The sexual dimorphism of epidermal growth factor receptor levels and the progressive increase in receptors during the second half of gestation reported here add additional complexities that need to be considered in developing models for their roles. It is interesting to speculate that epidermal growth factor and its receptors might be involved in one of the sexual dimorphic traits of newborn infants such as birth weight.[16] Additional data, however, are required to evaluate this possibility.

We thank Collin Osuamkpe for his help in the binding studies.

Immunohistochemical localization of epidermal growth factor receptor and myc oncogene product in human placenta: Implication for trophoblast proliferation and differentiation

Takeshi Maruo, M.D., and Matsuto Mochizuki, M.D.
Kobe, Japan

Cytologic localization of epidermal growth factor receptor and myc oncogene protein product in developing human placenta was analyzed by avidin/biotin immunoperoxidase techniques with a monoclonal antibody to epidermal growth factor receptor and an affinity purified polyclonal antibody to myc protein product. Epidermal growth factor receptor was found to be almost exclusively localized to syncytiotrophoblast, paralleling the immunohistochemical localization of human chorionic gonadotropin. Since epidermal growth factor has been shown to stimulate human chorionic gonadotropin and human placental lactogen production by cultured early placental tissue, the present finding that epidermal growth factor receptor was localized to mitotically inactive syncytiotrophoblast suggests a role for epidermal growth factor receptor in the induction of differentiated function of trophoblast rather than trophoblast proliferation. By contrast, myc protein product was found to be predominantly localized to cytotrophoblastic cells, paralleling the autoradiographic distribution of replicating cytotrophoblast identified by tritiated thymidine labeling of placental explant. A close similarity between the cytologic localization of myc protein product and tritiated thymidine labeling of placental explant suggests that myc protein expression is linked to trophoblast proliferation. Furthermore, immunohistochemical cellular levels of both epidermal growth factor receptor and myc protein product were most pronounced in early placenta and declined in term placenta. Thus myc protein product and epidermal growth factor receptor seem to play a crucial role in the induction of trophoblast proliferation and differentiation, respectively, during the development of human placenta. (AM J OBSTET GYNECOL 1987;156:721-7.)

Key words: Placental trophoblast, proliferation, differentiation, epidermal growth factor receptor, myc oncogene product

The trophoblast in early human placenta is composed of two distinct layers: an outer cell layer of multinuclear syncytiotrophoblast and inner cell layer of mononuclear cytotrophoblast. The cytotrophoblast displays highly proliferative and invasive properties very early in the first trimester. It is now evident that the syncytiotrophoblast is formed from the cytotrophoblast by a process of proliferation followed by cell fusion, and it displays little potential for proliferation.[1, 2] The syncytiotrophoblast is therefore regarded as mitotic end-stage cell derived from cytotrophoblast.

However, regulatory factors involved in processes of proliferation and differentiation of the placental trophoblast still remain to be elucidated. We have recently demonstrated that epidermal growth factor, a single chain polypeptide that is mitogenic for a variety of cultured cells, stimulates the production of both human chorionic gonadotropin and human placental lactogen by cultured early placental tissues,[2a] which suggests that epidermal growth factor may play a role in the induction of the differentiated function of trophoblast.

On the other hand, abundant evidence is now available that a number of the oncogenes of transforming viruses are related to normal growth factors and their receptors. Close similarity has been noted between platelet-derived growth factor and the translation product of v-sis oncogene[3] and between the cytoplasmic domain of epidermal growth factor receptor and the translation product of erb-B oncogene.[4] Of about 20 cellular oncogenes, myc oncogene is known to encode a protein localized to the nucleus of transformed cells. Several lines of recent evidence suggest a role for myc oncogene in cell proliferation.[5]

In the present study, attention was focused on the

expression of epidermal growth factor receptor and myc oncogene product in normal human placenta; the cytologic localization of these two factors in developing human placenta observed by the immunohistochemical techniques with a monoclonal antibody to epidermal growth factor receptor and an affinity-purified polyclonal antibody to human myc product was discussed in relation to their possible physiologic roles in the development of human placenta.

Material and methods

Material. First-trimester placentas were obtained from patients undergoing elective abortions at 6 to 10 weeks of pregnancy. Midterm placentas were obtained at the time of elective abortion at 20 to 22 weeks of pregnancy, whereas term placentas were obtained after spontaneous term deliveries with no medical complications.

Immunohistochemical staining. Placental tissues obtained were fixed in 4% buffered neutral formalin, dehydrated and embedded in paraffin. Sections, 5 to 6 μm in thickness, were deparaffinized and followed by standard histologic techniques.

Immunohistochemical staining was performed by avidin/biotin immunoperoxidase techniques[6] with the use of a polyvalent immunoperoxidase kit (Omnitags, Lipshaw, Michigan), which can be used with any primary antibody produced in rabbit, sheep, mouse, or guinea pig. A mouse monoclonal antibody against mouse epidermal growth factor receptor (Oncor Inc., Gaithersburg, Maryland), an affinity-purified sheep polyclonal antibody against human myc translation product (Oncor Inc.), and an affinity purified rabbit polyclonal antibody against hCGβ-carboxyl terminal peptide (Takeda Chemical Industries, Osaka, Japan) were used, respectively, as the primary antibodies in this study.

Tissue sections were first bleached in 3% hydrogen peroxide to block endogenous peroxidase and covered with protein blocking agent to minimize nonspecific antibody binding. Sections were then incubated with the respective primary antibody for 60 minutes at room temperature. The anti–epidermal growth factor receptor antibody, anti-myc protein antibody, and anti–hCGβ-CTP antibody were diluted 1:50, 1:20, and 1:50 before use, respectively. The first incubation with primary antibody was followed by the second incubation with biotinylated polyvalent antibody and by the third incubation with avidin-horseradish peroxidase. Then, chromogenic reaction was developed by incubating with freshly prepared solution of tetrahydrochloride-diaminobenzidine and hydrogen peroxide. Sections were counterstained with Harris hematoxylin.

The following control procedures were undertaken to assure specificity of the immune reactions. Adjacent control sections were subjected to the same immunoperoxidase method with the exception that the primary antibodies to epidermal growth factor receptor, myc product, and hCGβ–carboxyl terminal peptide were respectively replaced by nonimmune murine IgG (Miles, Elkhart, Indiana), nonimmune sheep IgG (Miles) and nonimmune rabbit IgG (Miles). Additional control was prepared by the omission of the biotinylated polyvalent antibody. In the above-mentioned controls, no positive staining was observed.

Autoradiography of placental explants exposed to tritiated thymidine. Fresh sterile placental tissues were rinsed with ice-cold Hanks balanced salt solution, and placental villous tissues dissected free of chorionic membranes were cut into approximately 1 mm^3 explants.

The placental explants were placed on filter papers within a plastic plate to which McCoy's 5a medium (Grand Island Biological Co., Grand Island, New York) containing 1 μCi/ml of tritiated thymidine (New England Nuclear, Boston, Massachusetts) was added. The explants were incubated at 37° C for 2 hours in an atmosphere of 95% air and 5% carbon dioxide. After the pulse incubation, the placental explants were subjected to autoradiography by a modified method of Kopriwa and Leblond.[7] Briefly stated, paraffin-embedded sections, 5 μm in thickness, were deparaffinized, hydrated, and dipped in undiluted Kodak liquid emulsion type NTB-2. After partial drying they were exposed at 4° C for 2 weeks in sealed Bakelite boxes containing Drierite and then developed in Kodak D-19 developer. The developed sections were stained with Harris hematoxylin.

Results

Cytologic localization of epidermal growth factor receptor. Fig. 1, *A*, shows the immunohistochemical staining for epidermal growth factor receptor in very early first-trimester placenta obtained at 6 weeks of pregnancy. Prominent staining with anti–epidermal growth factor receptor antibody was almost exclusively localized to the syncytiotrophoblasts. The immunostaining for epidermal growth factor receptor of the syncytiotrophoblasts was apparent not only on the cellular surface but also on the cytoplasma. Neither cytotrophoblastic cells nor interstitial cells of placental villi showed any appreciable staining for epidermal growth factor receptor.

The intensity of the immunostaining for epidermal growth factor receptor of placental cells varied over the course of pregnancy. The syncytiotrophoblasts of early first-trimester placenta demonstrated the most pronounced staining for epidermal growth factor receptor

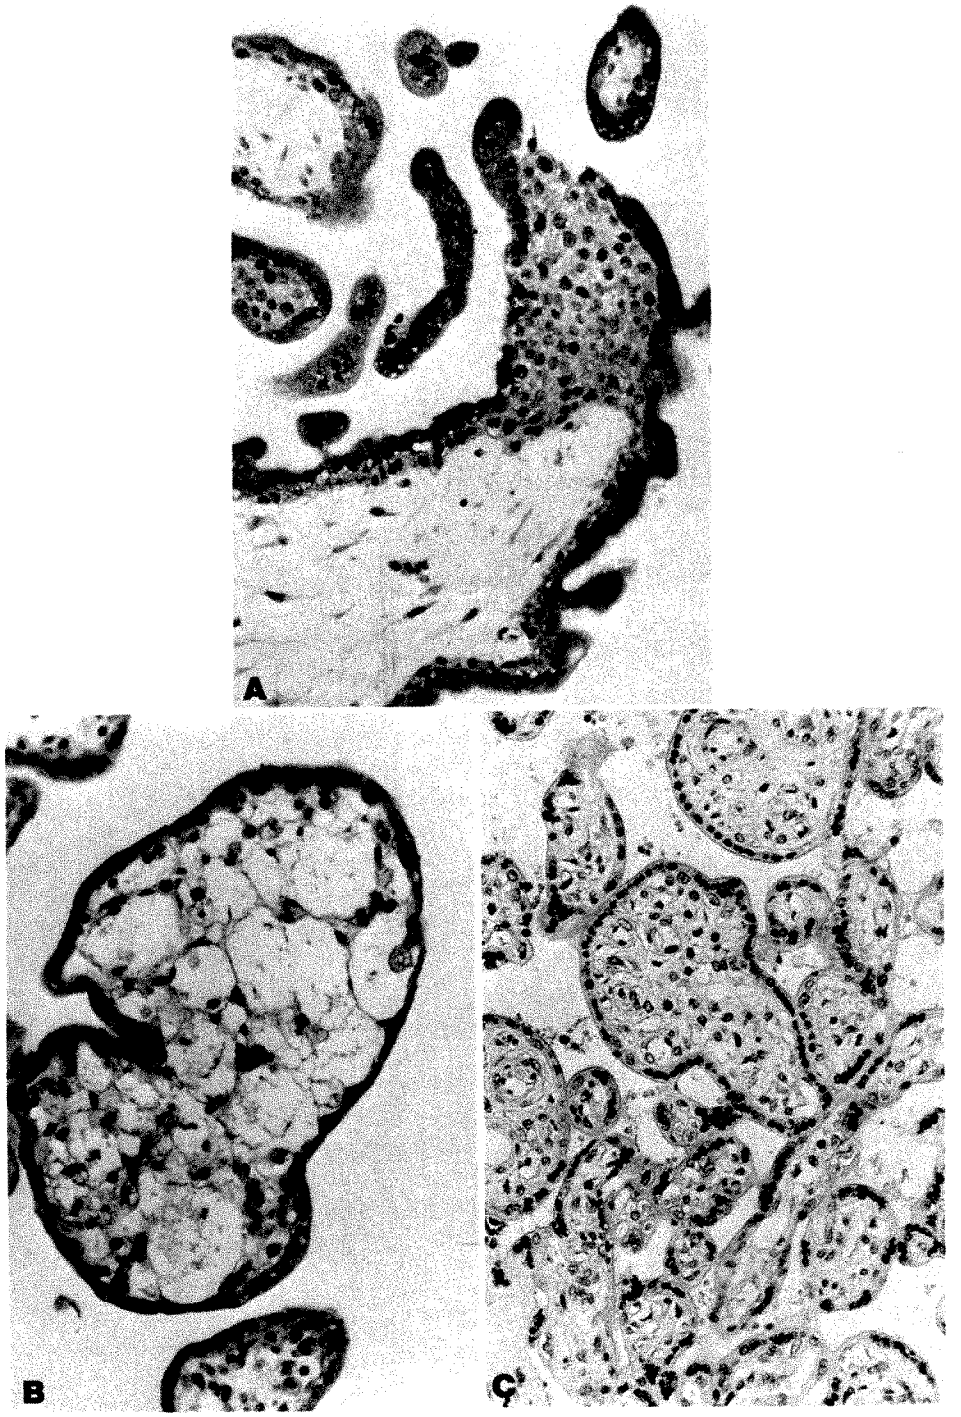

Fig. 1. Immunohistochemical localization of epidermal growth factor receptor in placental tissue sections over the course of pregnancy. Formalin-fixed paraffin-embedded sections of a 6-week placenta *(A)*, 22-week placenta *(B)*, and 40-week placenta *(C)* were stained by the avidin/biotin immunoperoxidase method with a monoclonal antibody directed against epidermal growth factor receptor. Most pronounced staining for the receptor was found in the early placental syncytiotrophoblasts, while the cytotrophoblastic cells were negative for appreciable staining. The staining intensity for epidermal growth factor receptor declined with the advancing ages of pregnancy. The lighter staining of nuclei is the hematoxylin counter stain. (× 200.)

Fig. 2. Immunohistochemical localization of hCGβ–carboxyl terminal peptide in early first-trimester placenta. Formalin-fixed paraffin-embedded sections of a 9-week placenta were stained by the immunoperoxidase method with anti–hCGβ–carboxyl terminal peptide antibody which is absolutely specific for human chorionic gonadotropin. Syncytiotrophoblasts showed pronounced staining with anti–hCGβ–carboxyl terminal peptide antibody, whereas cytotrophoblasts were negative for the immunostaining for human chorionic gonadotropin. (×200.)

(Fig. 1, *A*). In the case of midterm placenta obtained at 22 weeks of pregnancy (Fig. 1, *B*), the staining intensity for epidermal growth factor receptor of the syncytiotrophoblast was less prominent compared to that of early placenta, and term placenta showed a faintly positive staining for epidermal growth factor receptor (Fig. 1, *C*).

The immunohistochemical distribution of epidermal growth factor receptor observed in early placenta was very similar to that of human chorionic gonadotropin. The immunostaining with anti–hCGβ–carboxyl terminal peptide antibody was exclusively localized to syncytiotrophoblasts of developing human placenta (Fig. 2).

Cytologic localization of myc protein product. Fig. 3, *A* shows the immunohistochemical staining for myc protein product in early first-trimester placenta obtained at 6 weeks of pregnancy. Prominent staining with anti–myc product antibody was observed in the nuclei of the cytotrophoblastic cells. Although scarce staining for myc product was also apparent in the nuclei of the interstitial cells, no appreciable staining for myc product was found in the nuclei of syncytiotrophoblasts.

The intensity of the immunostaining for myc product in placental cells varied over the course of pregnancy. The most pronounced staining for myc product was observed in the cytotrophoblasts of early placenta (Fig. 3, *A*). In case of midterm placenta obtained at 22 weeks of pregnancy (Fig. 3, *B*), the staining intensity for myc product in the placental cells was less compared to that of early placenta. Term placental cells displayed no appreciable staining for myc product (Fig. 3, *C*).

Tritiated thymidine uptake by placental explants. Fig. 4 shows the autoradiogram of early placental explant exposed to tritiated thymidine for 2 hours. There were abundunt uptakes of tritiated thymidine in the nuclei of the cytotrophoblastic cells as well as interstitial cells. Tritiated thymidine uptake by the syncytiotrophoblasts was not encountered.

Comment

Epidermal growth factor is a polypeptide originally isolated from mouse submaxillary gland and later from human urine.[8] Although mouse and human epidermal growth factors differ slightly with regard to amino acid composition, they both are known to compete for the same receptor and demonstrate similar biologic activities.[9] It is now evident that epidermal growth factor receptor, a 170,000 molecular weight glycoprotein, is present in a variety of cell types.[10] Because of the participation of epidermal growth factor receptor in growth control and because of the close relationship of epidermal growth factor receptor to the erb-B oncogene translation product, it seems likely that there is the link between oncogenic stimulation of a cell and its normal growth-regulatory mechanism.[5,11]

The data presented in this paper shows that immu-

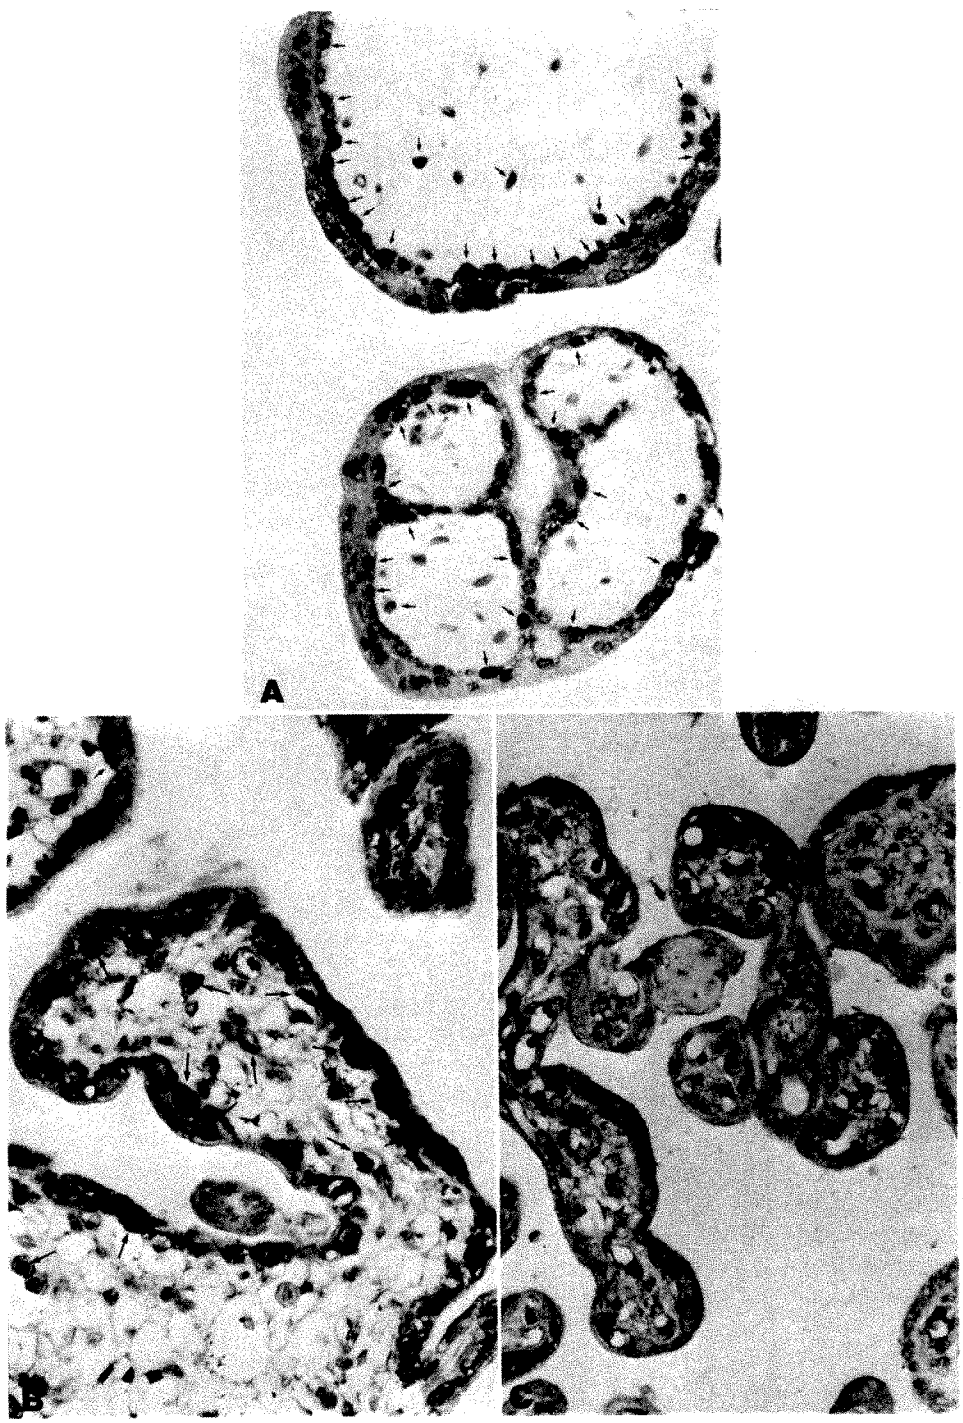

Fig. 3. Immunohistochemical localization of myc oncogene product in placental tissue sections over the course of pregnancy. Formalin-fixed paraffin-embedded sections of a 6-week placenta *(A)*, 22-week placenta *(B)*, and 40-week placenta *(C)* were stained by the avidin/biotin immunoperoxidase method with an affinity-purified antibody to myc protein product. Immunostaining for myc protein product was strongly positive in the nuclei of cytotrophoblasts and interstitial cells, whereas the nuclei of syncytiotrophoblasts were negative for the staining for myc protein product. The staining intensity markedly declined with the advancing ages of pregnancy. The lighter staining of nuclei is the hematoxylin counterstain. (×200.)

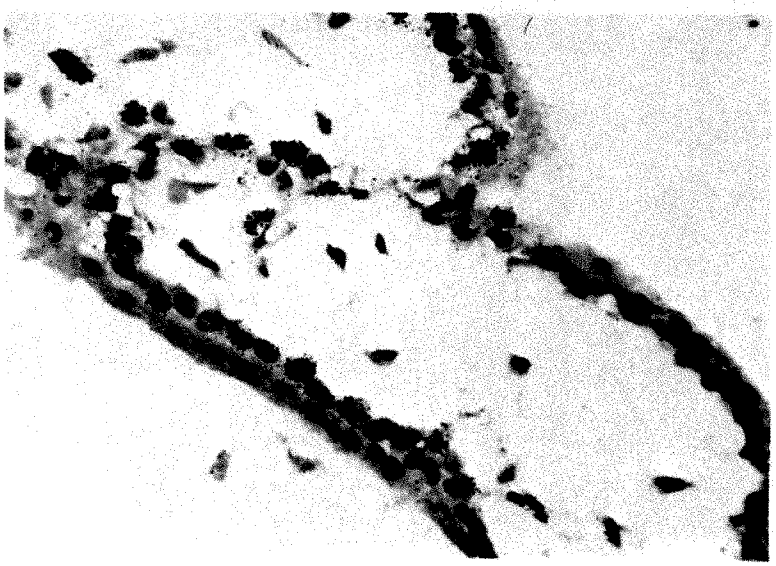

Fig. 4. Autoradiographic labeling of tritiated thymidine by early placental explants. Tissue explants from a 6-week placenta were exposed to tritiated thymidine (1 μCi/ml) for 2 hours. The formalin-fixed paraffin-embedded sections were subjected to autoradiography. Tritiated thymidine labeling was strongly positive in the nuclei of cytotrophoblasts, whereas there was no labeling of tritiated thymidine in syncytiotrophoblasts. (×400.)

nohistochemical cellular levels of epidermal growth factor receptor and myc oncogene product in human placenta vary considerably over the course of pregnancy and both the cellular levels are highest in early first-trimester placenta. We have also provided evidence that epidermal growth factor receptor in the placenta is almost exclusively localized to syncytiotrophoblast and is negative in cytotrophoblast, whereas myc oncogene product is predominantly localized to cytotrophoblast and is negative in syncytiotrophoblast. The inverse relation of the expression of epidermal growth factor receptor and myc oncogene product in early placenta and a decline in the cellular expression levels of both epidermal growth factor receptor and myc oncogene product in midterm and term placenta are of great interest when considering their possible physiologic roles in the control of placental development.

The localization of epidermal growth factor receptor on the cellular surface and cytoplasma of the syncytiotrophoblast of human placenta paralleled the immunohistochemical distribution of human chorionic gonadotropin and humman placental lactogen. The present immunohistochemical finding is in agreement with the autoradiographic data reported with iodine 125–labeled epidermal growth factor by Chengi and Rao,[12] who demonstrated that syncytiotrophoblast cells contain the epidermal growth factor receptors and that these receptors are present not only in outer cell membrane but also in intracellular organelles of human placental syncytiotrophoblasts. The fact that the mitotically active cytotrophoblasts were negative for epidermal growth factor receptor expression suggests that epidermal growth factor and its receptor may not be involved in the control of multiplication of trophoblasts. Instead, epidermal growth factor and its receptor seem to play a role in the induction of differentiated function of trophoblast, since epidermal growth factor has been already found to stimulate the production and secretion of human chorionic gonadotropin, α-human chorionic gonadotropin, and human placental lactogen by cultured early placental tissues.[2a]

On the other hand, the immunohistochemical localization of myc oncogene product to the nuclei of cytotrophoblasts of early placenta paralleled the autoradiographic distribution of replicating cytotrophoblasts identified by tritiated thymidine labeling of early placental explants. This indicates that there is a close correlation between the expression of myc oncogene product and cytotrophoblastic proliferation. The present immunohistochemical finding is in good agreement with the data of Pfeifer-Ohlsson et al.,[13] who demonstrated prominent expression of myc oncogene in cytotrophoblasts of early human placenta by in situ hybridization to human myc probe. The nuclear site of myc oncogene product suggests a fundamental regulatory role for the myc oncogene in the cytotrophoblasts. Furthermore, the highly increased expression of the myc oncogene product in early placental cytotrophoblasts, which display very proliferative phenotype, also supports a possibility that the protein product encoded by myc oncogene may play a crucial role in the trophoblast proliferation.

In this context, remarkable changes in the morphologic structure of developing human placenta are of interest. Although the trophoblast in early placenta is composed of two distinct layers, syncytiotrophoblast and cytotrophoblast, there is a steady reduction in the number of cytotrophoblastic cells as the placenta develops.[14] The cytotrophoblastic cells become much less prominent during the second trimester and in some villi appear to be absent during the third trimester. These morphologic changes of developing human placenta seem to be influenced by the expression pattern of myc oncogene.

Recently Goustin et al.[15] have reported that cultured cytotrophoblasts responded to exogenous platelet-derived growth factor by activation of the myc oncogene expression, suggesting that platelet-derived growth factor is also involved in the stimulation of cytotrophoblast proliferation. At the present time, however, it is not clear yet whether the induction of myc oncogene expression is a sufficient event for trophoblast proliferation. Nevertheless, on the basis of the results reported here it is apparent that myc oncogene product and epidermal growth factor receptor play a physiologic role independently in the induction of proliferation and differentiation of human placenta.

Circannual rhythms in steroid receptor concentration in gynecologic and breast cancers

Joseph T. Chambers, Ph.D., M.D., Roberta Lawrence, M.P.H., Neil MacLusky, Ph.D., Arnold Eisenfield, M.D., and Peter E. Schwartz, M.D.

New Haven, Connecticut

Both estrogen and progestin receptor concentrations vary in a predictive temporal pattern for breast cancer; in epithelial ovarian cancer a temporal rhythmic pattern is suggested for estrogen receptor concentration only. No pattern for either receptor is seen for endometrial cancer. (AM J OBSTET GYNECOL 1987;156:728-9.)

Key words: Circannual rhythms, steroid receptor concentration, breast cancer, ovarian cancer, endometrial cancer

The influence of time and season on biologic parameters is well established; however, the possible impact on oncology has only recently been noted and explored. The concentration of estrogen receptors in breast cancer has been shown to have a temporal predictive value along a 1-year scale and decreased toxicities have been established with various diurnal schedulings of chemotherapeutic drugs.[1] We investigated in a population of patients with histologically confirmed primary breast cancer, epithelial ovarian cancer, and endometrial cancer the concentration of estrogen and progestin receptor values in the tumors as a function of month of the year.

Material and methods

Estrogen and progestin receptor concentrations were determined by binding techniques with the use of radioactive steroid ligands as described elsewhere.[2] Receptor concentrations were determined in 859 tumor samples obtained from postmenopausal women with primary breast cancer, in 105 tumor samples from postmenopausal women with epithelial ovarian cancer, and in 159 tumor samples from postmenopausal women with endometrial cancer. All samples were obtained between October 1976 and September 1985. Statistical analysis was done with the use of a *t* test with Bonferroni correction for multiple comparisons and an analysis of variance to test the fit of the cosine curve to the data.

Results

We confirmed a previous report of a circannual rhythm in breast cancer estrogen receptor concentrations. The mean femtomoles of cytosol estrogen and progestin receptor per milligram of cytosol protein (±SEM) are plotted in Fig. 1 for the breast cancer samples.

The mean values for the period October through March were significantly higher than the mean values for the period April through September ($p = 0.012$) with a peak in December. The same trend was evident although slightly less significant when the zero values were eliminated, suggesting that the group of patients who had zero estrogen receptor values was not different from those who had positive receptor values. An analysis of variance showed that the amplitude of the fitted cosine curve was significantly higher in the winter months than in the summer months with a variation of 46%. Progestin receptor concentrations in the breast tumors showed temporal variations of a predicted pattern where the cosine fit was again significant ($p = 0.008$) (Fig. 1).

Estrogen receptor concentrations in epithelial ovarian cancer showed a seasonal variation with a peak in February through May and a trough in June through January; however, this was not statistically significant. The actual peak was bimodal in February and May (Fig. 1). There were only two ovarian cancer patients with zero estrogen receptor values so no separate analysis was executed on this set of data. There was no significant seasonal curve fit for the progestin receptor concentrations in the epithelial ovarian cancer samples.

Analysis showed that no significant cosine curve could be fitted to the estrogen or progestin receptor concentrations along a time series for the endometrial cancer data.

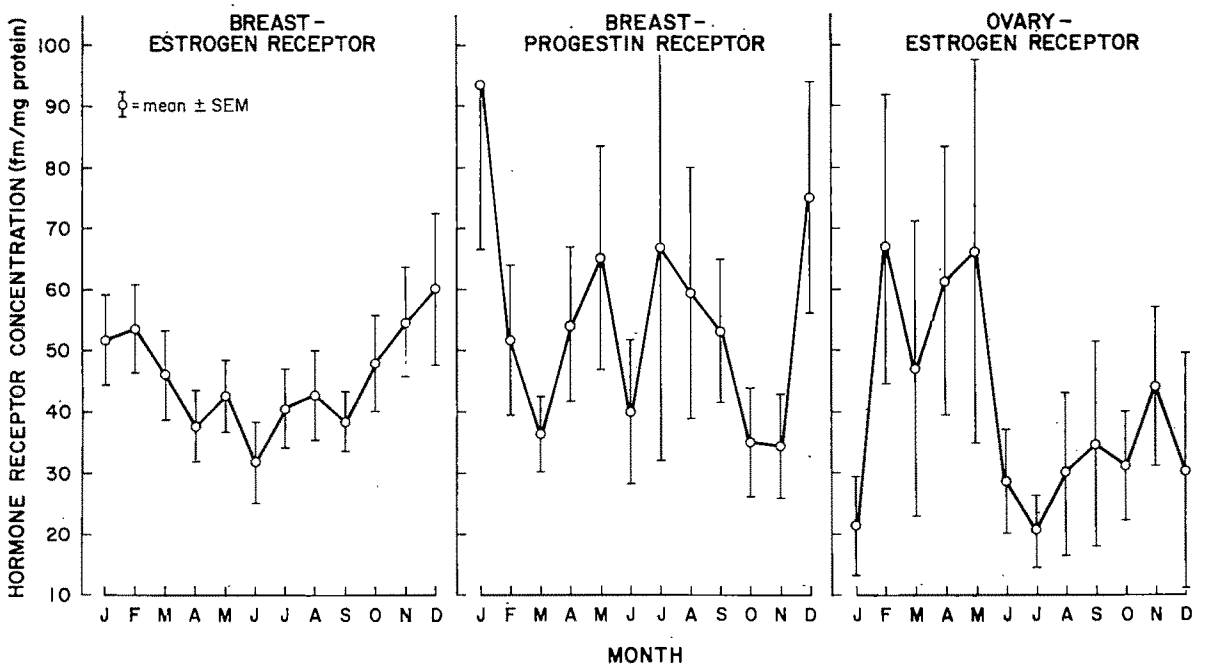

Fig. 1. Steroid receptor concentrations in breast and ovarian cancers as a function of the month.

A test for linear trend was included in all models that resulted in a significant negative trend during the period of years for all cancer types ($p = 0.001$ in breast cancer, $p = 0.0035$ in ovarian cancer, and $p = 0.0147$ in endometrial cancer). The reason for this overall negative trend remains uncertain. Perhaps there were population differences in the women over the years. A more likely possibility, however, is that the effect may be due to improvements in the receptor assay designed to minimize the contribution from low-affinity binding components. These modifications, which have been detailed previously,[2] may have given rise to the observed negative trend as a result of a slight overestimation of receptor concentrations in the earlier assays (1976 to 1979). Nevertheless, the predictive patterns noted above remain valid, since the same circannual trends are apparent irrespective of the years in which the data were obtained.

In conclusion, our observations confirm a temporal predictive pattern of estrogen receptor concentrations in breast cancer with a trough in April and a peak in December and also show a similar pattern for progestin receptor concentrations. However, in epithelial ovarian cancer, we observed a different seasonal pattern, the peak value for the estrogen receptor values being in the early part of the year compared with the trough in the midyear, but this was not statistically significant. The influence of the environment from a temporal standpoint may need to be further explored in determining the results from current treatment protocols in oncology.

An improved human tumor stem cell assay in ovarian cancer

Peter G. Rose, M.D., Antoinette Koolemans-Beynen, M.S., John G. Boutselis, M.D., John P. Minton, M.D., Ph.D., and George E. Milo, Ph.D.
Columbus, Ohio

To evaluate the effect of improved growth rates of ovarian cancers in the human tumor stem cell assay and its value in predicting clinical chemotherapy response, we studied 59 assays in 54 patients. A total of 81.6% of solid specimens and 85.7% of ascites specimens were successfully cultured and yielded an overall growth rate of 82.9%. Simultaneous primary and metastatic cultures were concordant for chemosensitivity in 80% (n = 16). The patients were evaluated for previous chemotherapy, residual volume of tumor, histologic type, and grade, and these were not statistically different between clinical responders and nonresponders. In vivo–in vitro correlations were made in 27 patients and yielded a predictive response of 13% and predictive resistance of 86% at 70% colony inhibition and 31% and 71% at 50% colony inhibition. Improved growth rates therefore did not result in better predictive correlations. The reported experience in ovarian cancer is summarized and the current status of the human tumor stem cell assay is reviewed. (Am J Obstet Gynecol 1987;156:730-4.)

Key words: Stem cell assay, chemotherapy, ovarian cancer

The development of effective chemotherapy remains the most significant advance in the treatment of ovarian cancer in the last three decades. However, until recently, the selection of chemotherapeutic agents has been based on clinical experience. The development of the in vitro soft agar assay system in 1955[1] and its clinical application to human tumors in 1972[2] have suggested new avenues for the selection of a chemotherapeutic agent for patients on an individual basis determined by in vitro sensitivity. In addition to its ability to indicate specific tumor sensitivity, the assay could potentially save valuable time that would be lost on ineffective treatment. It also opens the possibility of in vitro testing of new chemotherapeutic drugs on human tumor cells before clinical application.

Numerous clinical reports suggest an in vitro–in vivo sensitivity correlation of 40% to 88% and an in vitro–in vivo resistance correlation of 90% to 100%.[3-6] In most of these studies, success rates in establishing growth in soft agar ranges from 25% to 50%.[7] The Ohio State University Clonogenic Assay Laboratory, established in 1981, has performed more than 900 human tumor stem cell assays with a variety of tumors. The modified procedure has resulted in an improved success rate of more than 80%. The purpose of this study was to investigate correlation of clinical and assay data in the presence of these improved culture conditions. The data presented in this paper include the results of 59 successful assays on ovarian tumor specimens, representing 54 patients. A retrospective in vivo–in vitro correlation is reported.

Material and methods

Single cell preparation. Ovarian carcinoma specimens were obtained from patients from the following Columbus and area hospitals: The Ohio State University Hospitals (n = 42), Riverside Methodist Hospital (n = 4), Grant Hospital (n = 4), Mansfield General Hospital (n = 3), and Mt. Carmel West Hospital (n = 1) and assayed according to a modified procedure of the human tumor stem cell assay described by Hamburger and Salmon.[2] Briefly, the specimens were collected in medium under sterile conditions, transported to the laboratory, and processed within 24 hours. The tissue was minced and washed two times in minimum essential medium (K. C. Biological Inc., Lenexa, Kansas) containing 5% fetal bovine serum (Hyclone, Sterile Systems, Logan, Utah) and gentamicin (50 μg/ml). The tissue fragments were transferred into a Cellector sieve (Bellco, Vineland, New Jersey) equipped with a triple screen (120 mesh) and further minced with scalpels. Optimal viability was ensured by repeated rinsing with minimum essential medium. The resultant single cell suspension was centrifuged at 750 × g and then resuspended in minimum essential medium and a cell count taken. Cell density was adjusted to 1.5×10^6 cells per milliliter.

Ascites specimens were collected in sterile containers without heparin and the cells were pelleted by centrifugation at 750 × g. The cell pellet was resuspended in minimum essential medium and transferred to a Cellector sieve and processed as above. If a specimen did not yield a sufficient number of cells to complete an

assay, intermediate short-term monolayer cultures were set up in an effort to increase cell count.

Drug incubation. The following chemotherapeutic agents were prepared to achieve final concentrations equivalent to peak plasma concentrations as calculated by Alberts and Chen[8] against ovarian tumors: (1) Adriamycin, 0.04 μg/ml; (2) cisplatin, 0.2 μg/ml; (3) 5-fluorouracil, 6.0 μg/ml; (4) methotrexate, 100.0 μg/ml; (5) vinblastine, 6.0 μg/ml; (6) VP-16, 3.0 μg/ml; (7) aclacinomycin, 0.1 μg/ml; (8) dihydroxyanthracenedione, 0.1 μg/ml; (9) melphalan, 1.0 μg/ml; (10) hexamethylmelamine, 1.0 μg/ml; (11) mitomycin C, 1.0 μg/ml.

One milliliter of cell suspension and 0.35 ml of minimum essential medium were added to each test tube containing 0.15 ml of the appropriate 10× drug solution. The cell-drug mixture was gently stirred in a vortex mixer and then incubated for 1 hour at 37° C and 4% carbon dioxide. Two tubes containing 0.15 ml of phosphate-buffered saline solution were included for controls.

Media preparation and cell plating. Difco Bacto-Agar (Difco, Detroit, Michigan) was washed four times in demineralized water and brought into solution as previously reported.[9] Feeder layer and plating media were prepared according to the protocol of the Southwest Oncology Group, except that the ratio used was 2:1.[10]

At the conclusion of the 1-hour drug exposure period, the cells were washed by adding 5 ml of minimum essential medium to each drug incubation tube and the cells were removed by centrifugation. The supernatants were aspirated and replaced with 0.3% agar–plating medium mixture. The cells were dispersed by trituration and layered on top of each 0.5% agar feeder layer in 60 mm plastic Petri dishes as previously described.[9] Each experiment was performed in triplicate. Cultures were examined on day 0, and all clumps were identified for subtraction from the final colony count. In our laboratory, cell clumps were rare and occurred at a frequency of <1 per 50,000 cells plated. After 12 to 20 days of incubation at 37° C and 4% carbon dioxide in a humidified atmosphere, the formed colonies were counted with an inverted phase-contrast microscope. Percent inhibition of tumor colony formation was calculated with the following formula:

$$\text{Percent inhibition} = 1 - \frac{\text{number of colonies exposed}}{\text{number of colonies in control}} \times 100\%$$

A successful assay would contain at least 25 colonies in the control plates, each measuring ≥60 μm in diameter, or containing no less than 30 cells.[10]

Clinical evaluation and in vitro–in vivo correlation. Pathology slides of all patients were reevaluated and tumors were graded according to the classification of the International Federation of Gynecology and Obstetrics. The clinical records were reviewed and patients were classified as complete responders, partial responders, or nonresponders on the basis of objective criteria for tumor response defined by the World Health Organization. Patients were excluded if they failed to receive at least two courses of a chemotherapeutic agent for which they had been tested. Thus clinical and in vitro data for 27 patients could be correlated. Percent inhibition of tumor colony formation in vitro was analyzed at both >50% and at >70% inhibition levels as reported elsewhere (see Table III). Statistical analyses were completed with a χ^2 test.

Results

Eighty-four ovarian specimens were submitted from November 1981 through September 1985. Nine specimens had inadequate cell counts for soft agar chemosensitivity testing, but one was salvaged by intermediate culturing as described. The 76 specimens tested consisted of 60 solid tumors and 16 ascites specimens. Two solid tumors (3.3%) and two ascites specimens (12.5%) could not be evaluated because of bacterial contamination. Subsequent to tissue processing and plating, fungal contamination occurred in <4% of the total 2161 Petri plates. Clonogenic assays were successful in 81.6% of the solid specimens and 85.7% of

the ascites specimens tested, yielding an overall growth rate of 82.9%. Cloning efficiencies, the percentage of cells seeded that resulted in colony formation, ranged from 0.01% to 0.6% with a mean value of 0.15%.

The following chemotherapeutic agents were routinely tested: Adriamycin, cisplatin, methotrexate, vinblastine, 5-fluorouracil, and dihydroxyanthracenedione. Additional agents tested at the physician's request included VP-16, melphalan, hexamethylmelamine, mitomycin C, and aclacinomycin. Cyclophosphamide was not tested bcause it requires metabolic activation to be effective. The results are listed in Table I.

Fifty-nine successful assays were performed on specimens from 54 patients with primary ovarian cancer (50 epithelial, one granulosa, one dysgerminoma, and two carcinosarcoma).

Twenty-seven patients with Stage III or IV disease could be evaluated for response. Histologic type, grade, previous therapy status, clonogenic assay results, and clinical response are summarized in Table II. Evaluation correlating in vitro results with clinical outcome correctly predicted a positive response in 13% of the cases and a negative response in 86% at the 70% to 100% inhibition level. At the 50% to 100% inhibition level, these values were 31% and 71%. This distribution is not statistically significant.

The remaining 27 patients had to be excluded from the study. Seventeen of them received less than one course of a chemotherapeutic agent tested or were treated exclusively with agents not tested in the assay. Two patients who are currently receiving therapy are not evaluable. Also excluded were six patients who were clinically and radiologically without evidence of disease but who refused a second-look laparotomy. Two of these patients had recurrent disease 6 and 17 months after cessation of chemotherapy. Another patient with Stage IIA disease, treated with total abdominal hysterectomy, bilateral salpingo-oophorectomy, omentectomy, and chemotherapy, could not be evaluated in the absence of measurable primary disease. Last, one patient was treated elsewhere for 19 months with clinical response but without objective evaluation until she died of disease.

Comment

Improved conditions in processing and culturing tumor tissue have resulted in successful growth rates for ovarian carcinomas of 82.7%. Significant improvements include standardized tissue collection procedures during operation by a tumor procurement service. Tissue dehydration is avoided by repeated rinsing of the tumor fragments with minimum essential me-

dium, and trauma is minimized by mincing the tissue with scalpels on a triple screen sieve. The low molecular weight polysaccharide toxicity of the agar[11] is reduced by repeated washing with demineralized water before autoclaving, and the modified ratio of two parts feeder layer to each one part plating layer favors growth. In spite of increased success rates in cloning the tumors, the assay's predictive power has not improved. A review of the literature presenting in vivo–in vitro correlation in ovarian cancer is summarized in Table III. Individual studies with success rates varying between 25% and 50%[7] show a high degree of correlation between negative human tumor stem cell assay results and clinical failure. Positive assay results, defined as either >50% inhibition or >70% inhibition, indicate predictability of clinical response in 60% of the cases. Cumulative results of 355 assays yield a predictive value of 93.4% for a negative human tumor stem cell assay and 64.8% for a positive assay (Table III).

Most correlation studies share common methodologic errors. Multiple assays performed on specimens from a single patient introduce serious sampling errors and compromise the statistical analysis of the data and the predictive value of the assay. Many patients have received agents not tested in the assay, notably cyclophosphamide (Cytoxan), which requires metabolic activation. In addition patients are often treated with multiple chemotherapeutic agents, and the significance of in vitro sensitivity to single agents, in contrast to multiple drugs, is not known. Alberts et al.[12] describes one of the few prospective studies reported in the literature to date. The in vitro directed therapy with one to three agents in which a 50% clinical response rate was achieved was significantly better ($p = 0.05$) than empiric therapy, although type of previous chemotherapy, volume of residual disease, and type of empiric therapy were not reported. Despite these limitations this study provides the greatest support for the human tumor stem cell assay. None of the authors has randomized previously untreated patients to chemotherapy directed by human tumor stem cell assay versus cisplatin and cyclophosphamide with or without Adriamycin with or without hexamethylmelamine.

Theoretical objections against the human tumor stem cell assay have recently been reviewed by Weisenthal and Lippman.[13] Principal arguments can be placed in four categories. First, cell cultures may represent only certain cell populations of the tumor. Resultant predictions of chemosensitivity may not take into account in vivo proliferation of cells that would not grow in the soft agar system. Arbuck et al.[14] described discrepancies between human tumor stem cell assay results of primary and metastatic specimens submitted simultaneously from the same patient. In our experience 16 paired observations (n = 6) indicate agreement in more than 80%. In one case the primary specimen did not grow, and only the metastatic tumor could be cloned successfully.

Second, in vitro drug concentrations and exposure times differ from in vivo drug protocols. Alberts et al.,[8] studying human subjects, established pharmacokinetic parameters for the most commonly used anticancer drugs and applied these findings to the clonogenic assay. In most studies drug exposure time in the assay is limited to 1 hour. Experiments with continuous exposure have been performed, but increases in colony formation inhibition were found to be minimal in most cases, possibly because of deactivation of the agents tested under culture conditions. In contrast to the human body, the assay is not a homeostatic system and drugs cannot be replenished nor can toxic waste products be eliminated.

Third, the percentage of tumor colony formation inhibition in vitro may not be relevant to clinical response. The effectiveness of a chemotherapeutic agent depends on the fraction of cell kill. From a mathematical viewpoint, effective agents must have a fractional cell kill of 99 to 99,999 (two to five log). The significance level for percent inhibition in the human tumor stem cell assay has been determined by in vitro–in vivo correlation,[8] but many factors affecting clinical response (previous chemotherapy, volume of residual disease, specific tumor histologic type and grade) must be controlled to make such a correlation valid. Tumor colony formation inhibition is not synonymous with cell killing, and cells may be arrested in a dormant yet viable state with potential for reactivation.

Finally, the assay ignores immunologic factors.

In this study clinical responders and nonresponders were not statistically different with respect to previous chemotherapy, treatment with drugs not tested in the assay, and volume of the residual tumor (see Table II). For disease evaluation all complete responders and 82% of the partial responders had a second-look laparotomy. Arbuck et al.[14] suggested that validation of the human tumor stem cell assay would require a prospective study of 500 patients to detect a 15% differential response rate. Most researchers agree that a single-agent human tumor stem cell assay study is desirable, but few clinicians are willing to risk negative results with single-agent therapy during an era in which combination therapy with drugs such as cisplatin, Cytoxan, Adriamycin, and hexamethylmelamine have become the standard[15, 16] with clinical response rates of 65% to 70%. The use of the human tumor stem cell assay seems more appropriate in patients who have failure of primary therapy with a regimen containing cisplatin, since second-line therapy in these patients is poor. Future prospective studies are indicated.

We would like to acknowledge the efforts of Dr. Kathryn Clausen for review of pathologic specimens. We would also like to acknowledge the following physicians for submitting specimens to our assay laboratory: Dr. J. Bell, Riverside Methodist Hospital; Dr. M. Cooperman, The Ohio State University Hospitals; Dr. D. Dewald, Mansfied General Hospital; Dr. G. Johnston, The Ohio State University Hospitals; Dr. L. Laufman, Mansfield General Hospital; Dr. T. Martin, The Ohio State University Hospitals; Dr. T. Nims, Grant Hospital; Dr. N. Teteris, The Ohio State University Hospitals; Dr. T. Williard, Mt. Carmel West Hospital, and Dr. F. Zuspan, The Ohio State University Hospitals.

Ontogeny of pituitary β-endorphin and related peptides in the human embryo and fetus

F. Facchinetti, M.D., A. R. Storchi, M.D., F. Petraglia, M.D., G. Garuti, M.D., and A. R. Genazzani, M.D.

Modena, Italy

In this study we evaluated the presence of proopiomelanocortin-related peptides (β-lipotropin, β-endorphin, and γ-endorphin) in five embryos (5 to 10 weeks of pregnancy) and 11 fetal pituitaries (15 to 25 weeks) by means of high-performance liquid chromatography coupled with specific radioimmunoassays. Tissues were collected at laparotomy for ectopic pregnancy (five embryos) or after spontaneous (seven) or prostaglandin-induced (four) abortion. β-Endorphin and β-lipotropin were present starting at the seventh week of pregnancy while γ-endorphin appeared only in the second trimester. During embryonic life opioid activity was limited to the cephalic portion. The three peptides, but little, if any, acetylated 1-31 β-endorphin, were recognized in the fetal pituitary throughout the second trimester, at which time β-lipotropin and β-endorphin showed constant values in spite of increasing γ-endorphin concentrations. β-Lipotropin was the predominant peptide in both embryonic and fetal life. In conclusion, the three peptides related to proopiomelanocortin were expressed from the precursor at different times throughout development. By the beginning of the second trimester the pituitary processing of proopiomelanocortin is similar to that of adult life and the functional activity of the anterior lobe seems to prevail over that of the "fetus-related" neurointermediate lobe around the twenty-fifth week of pregnancy. (Am J Obstet Gynecol 1987;156:735-9.)

Key words: Embryo, anterior pituitary, neurointermediate lobe, β-endorphin, β-lipotropin, γ-endorphin

The activity of the proopiomelanocortin-related opioid system undergoes important changes during pregnancy as suggested by the increased adrenocorticotropic hormone and β-endorphin levels in the maternal circulation[1] and by the changing number and affinity of naloxone binding sites in uterine rat membranes.[2] In addition to the maternal pituitary and placenta, whose opioid secretory ability has been demonstrated,[3] the fetal pituitary is believed to contribute to the increase in opioid peptide levels.

Immunohistochemical data indicate the presence of adrenocorticotropic activity from the seventh week of pregnancy[4] while no β-lipotropin, another proopiomelanocortin-related peptide, was found. On the other hand, Begeot and Dubois[5] recently reported the coexistence of several proopiomelanocortin-related peptides in fetal pituitary corticotropes.

Biochemical studies of opioid ontogeny in human material are scanty and contradictory. Some authors[6] reported a large amount of β-endorphin in the fetal pituitary, and others[7] described the presence of β-lipotropin but were unable to demonstrate authentic β-endorphin in the 11 to 19 weeks' gestational age range. Moreover, with the use of sophisticated techniques it has been ascertained that the fetal pituitary does not contain true α-melanocyte–stimulating hormone, as reported several years ago by Silman et al.,[8] but its desacetylated form, adrenocorticotropic hormone 1-13 amide.[9] More recently, the presence of α-endorphin and γ-endorphin, two N-terminal derivatives of β-endorphin (1-16 and 1-17, respectively), has been verified in the human pituitary gland.[10]

In this study therefore we evaluated β-lipotropin, β-endorphin, and γ-endorphin in embryos and fetal pituitaries up to the beginning of the third trimester by means of high-performance liquid chromatography coupled with specific radioimmunoassays.

Material and methods

Tissue collection. Five embryos at 5 to 10 weeks of pregnancy were obtained at operation in ectopic pregnancies. The smallest embryo had a rostral-caudal length of 10 mm, ascribed to a gestational age of 4.7 weeks. In two specimens, the caudal portion was divided from the rostral one and processed separately.

Eleven whole pituitaries were collected from fetuses between 15 and 25 weeks of pregnancy. Seven of the 11 fetuses were spontaneously aborted, and four were delivered after a prostaglandin induction of labor performed because of rubella infection. Every tissue was

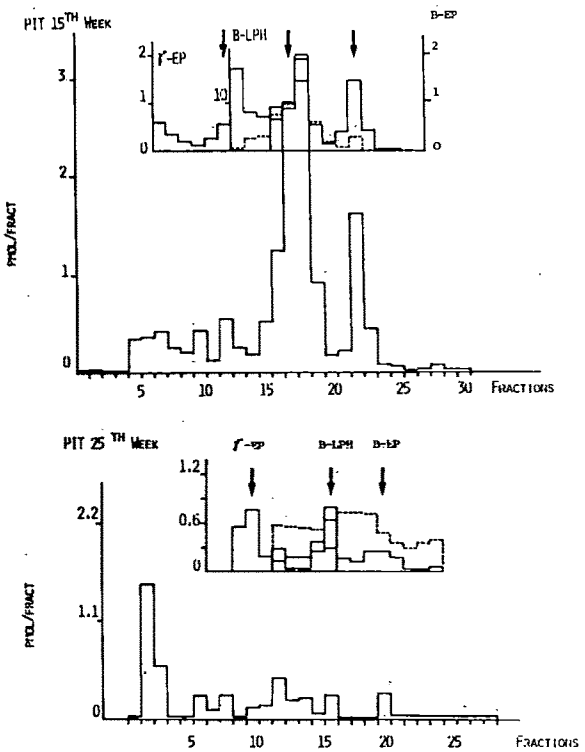

Fig. 2. Chromatogram of β-endorphin–like immunoreactivity and specific γ-endorphin *(γ-EP)*, β-lipotropin *(B-LPH)*, and β-endorphin *(B-EP)* immunoreactivity in two whole pituitaries obtained from a fetus at the fifteenth week and a fetus at the twenty-fifth week of pregnancy.

boiled for 10 minutes in 0.05 mol/L acetic acid in order to destroy proteases and then homogenized with a Polytron. After two successive centrifugations at 4000 × g for 15 minutes, clear supernatants were stored at −20° C until assayed. The pellets were treated with 1 mol/L sodium hydroxyde and submitted to a protein content evaluation with the use of the Folin phenol reagent.

High-performance liquid chromatography. Homogenates were injected in a high-performance liquid chromatography apparatus (Waters, Milford, Massachusetts) consisting of two pumps (Model 510), an ultraviolet detector (Model 440), and a gradient controller (Model 680). A reverse phase C-18 column (μBondapack, 39 by 300 mm, 10 μm size) was eluted in a linear gradient from 25% to 40% acetonitrile in 0.01 mol/L hydrochloric acid, for 15 minutes, at a flow rate of 1.5 ml/min. For each sample, 30 fractions were collected (each for 30 seconds), evaporated to dryness, and redissolved in 1 ml of 0.12 mol/L phosphate buffer, pH 7.4, and 0.1% bovine serum albumin.

In order to evaluate the amount of material sticking on the column, 1 ng of each of the three peptides was injected into the system and processed as described above. This experiment was replicated five times. Recoveries were 88.1% ± 10.4% for β-endorphin, 91.5% ± 17.3% for β-lipotropin, and 79.4% ± 12.8% for γ-endorphin.

Radioimmunoassays. Each fraction was tested for its β-endorphin–like immunoreactivity with the use of the anti–β-endorphin serum B4 (kindly donated by Dr. V. M. Wiegant, Utrecht, The Netherlands), which cross reacts with many β-endorphin–related peptides including 1-16 β-endorphin (260% on a molar basis), 1-17 β-endorphin (450%), 1-26 β-endorphin (11.5%), 1-27 β-endorphin (9.5%), and acetyl β-endorphin (100%). Thus, according to this β-endorphin immunoreactivity and in view of the retention times (Table I) of γ-endorphin, β-lipotropin, and β-endorphin, fractions were retested for their immunoreactivity with the use of appropriate iodinated peptides and specific antisera kindly donated by Dr. V. M. Wiegant (γ-endorphin) and by Professor C. H. Li (β-endorphin and β-lipotropin, San Francisco, California). Details of the different radioimmunoassays were previously reported.[2, 11]

Results

In the embryo of 4.7 weeks' gestation neither β-endorphin–like immunoreactivity nor specific peptides were detected. β-Endorphin (195.9 ± 57.7 fmol, mean ± SE) and β-lipotropin (569.6 ± 64.9 fmol)

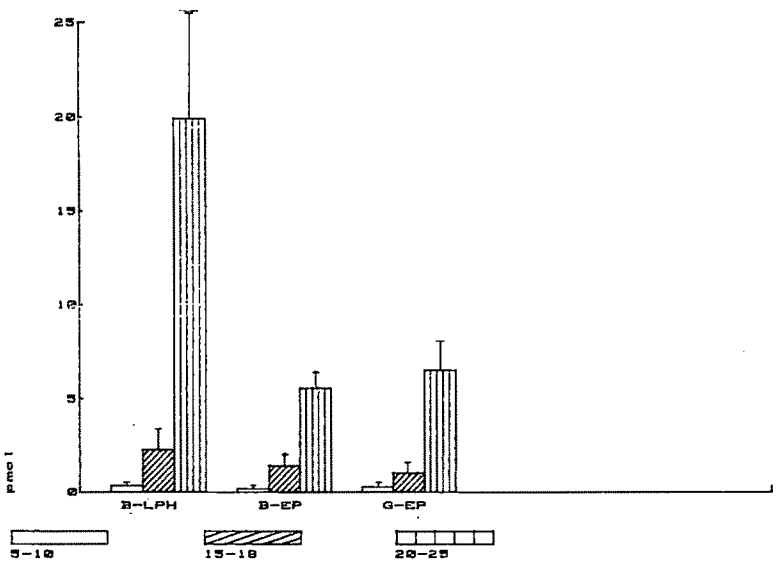

Fig. 3. Total content (mean ± SD) of β-endorphin *(B-EP)*, γ-endorphin *(G-EP)*, and β-lipotropin *(B-LPH)* in embryos and fetal pituitaries from 5 to 25 weeks of pregnancy.

were found but no γ-endorphin was present in embryos until the tenth week of pregnancy with one exception. This latter sample was the only one showing a poor β-lipotropin content.

During the embryonic period the peptides were measured only in the cephalic portion and no immunoreactivity was found in the caudal one (Fig. 1).

High amounts of the three proopiomelanocortin-related peptides were present in the fetal pituitaries; immunoreactive β-lipotropin, β-endorphin, and γ-endorphin elute at the same retention times as standard molecules (Fig. 2).

The total content of β-endorphin, β-lipotropin, and γ-endorphin in embryos and fetal pituitaries is shown in Fig. 3. There is a progressive increase of the three peptides throughout pregnancy, but the rates of such increases are different. This is reflected by the absence of correlation between β-lipotropin and β-endorphin, β-lipotropin and γ-endorphin, and γ-endorphin and β-endorphin during pituitary development.

Interestingly enough, the β-lipotropin/β-endorphin ratio increases from 1.41 ± 0.37 at the beginning of the second trimester to 4.4 ± 1.40 ($p < 0.5$) in the pituitaries of 22 to 25 weeks' gestational age. The opposite occurs in the β-endorphin/γ-endorphin ratio, which decreases from 1.64 ± 0.58 to 1.08 ± 0.29. In fetal pituitary extracts (Fig. 2), no β-endorphin–like immunoreactivity (lower part of each panel) was detected in fractions 24 to 30, corresponding to the elution pattern of acetyl β-endorphin.

Table I. Retention times, in minutes (mean ± SD of at least 10 determinations) with the use of a μBondapack C-18 RP column eluted from 25% to 40% acetonitrile in 0.01 mol/L hydrochloric acid, in 15 minutes at a flow rate of 1.5 ml/min

Peptide	*Retention time (min, mean ± SD)*

Comment

These data provide evidence that β-endorphin, β-lipotropin, and γ-endorphin are present in the fetal pituitary throughout development. Time-related differences in the appearance of the three peptides in the pituitary exist. β-Endorphin and β-lipotropin appeared in the seventh week when they were present in the cephalic portion, indicating that at that moment proopiomelanocortin activity was confined to pituitary and central nervous system structures.

Few studies exist about the ontogeny of β-lipotropin and β-endorphin in the human embryo. Some authors reported the presence of β-endorphin[6] and β-lipotropin[7] in the pituitary in the eleventh week of pregnancy when bioassayable adrenocorticotropic hormone is also demonstrable.[11] Immunohistochemical data have indicated positive staining for β-endorphin early in development, that is, in the seventh week,[4] and the present

biochemical characterization agrees completely with such a study.

γ-Endorphin, a product of β-endorphin cleavage that is present in brain synaptosomal membranes and in the adult pituitary,[14] is undetectable in all but one embryo, thus suggesting that the proopiomelanocortin-enzymatic system needs further maturational processes in intrauterine life in order to be fully expressed.

It was assumed that during fetal life pituitary proopiomelanocortin undergoes two successive cleavage steps: the first one to produce adrenocorticotropic hormone and β-lipotropin and the second one further cleaving these two peptides to give α-melanocyte–stimulating hormone and β-endorphin, respectively.[8] The second step of proopiomelanocortin processing is typical of the intermediate lobe of the rat pituitary,[13] a structure lacking in the human adult pituitary but well defined during fetal life. However, in whole fetal pituitaries and embryos, β-lipotropin was the predominant peptide and the β-lipotropin/β-endorphin ratio increased until the end of the second trimester, suggesting that the first proopiomelanocortin cleavage step is the most active in this period of life.

Gibbs et al.[14] superfused the fetal pituitary and demonstrated that the anterior lobe acquires its responsiveness to corticotropin-releasing factor just after the twentieth week of pregnancy. On the other hand, the neurointermediate lobe releases β-endorphin only after a potassium chloride–induced cell depolarization, and no changes occurred with corticotropin-releasing factor or dopamine. Thus the major peak of β-lipotropin obtained from whole pituitaries until the end of the second trimester can be interpreted as originating from the anterior lobe. We suggest that as early as the embryo the enzyme pattern for proopiomelanocortin cleavage is similar to that existing in the adult pituitary. Other authors,[15] studying human adrenocorticotropic hormone ontogeny, also concluded that the anterior lobe matures before the intermediate one. Another feature of the neurointermediate lobe (in the rat) is the acetylation of proopiomelanocortin and its related peptides, a process that inactivates the ability to bind opiate receptors.[16] It is uncertain if acetylation occurs in the human being and we found little immunoreactivity, if any, related to acetyl β-endorphin.

In conclusion proopiomelanocortin-related peptides are evident early in development and both β-endorphin and β-lipotropin were present in embryonic life, between 5 and 7 weeks, while smaller fragments of β-endorphin, such as γ-endorphin, have a delayed appearance. By the beginning of the second trimester the pituitary processing of proopiomelanocortin is similar to that of the adult and the functional activity of the anterior lobe seems to prevail over that of the "fetus-related" neurointermediate lobe around the twenty-fifth week of pregnancy.

We are indebted to Dr. V. Wiegant and Dr. P. Burbach of the Rudolf Magnus Institute for Pharmacology, University of Utrecht, The Netherlands, for their advice about high-performance liquid chromatography techniques and for the supply of the quoted materials. We also acknowledge Prof. A. E. Panerai, of the Istituto di Farmacologia, Università di Milano, for his help in performing our first high-performance liquid chromatography runs. Finally, the generous supply of anti–β-endorphin and anti–β-lipotropin sera from Prof. C. H. Li, of the Hormone Research Laboratory, University of California, San Francisco, is also acknowledged.

Effects of maternal anemia on cardiac output, systemic oxygen consumption, and regional blood flow in pregnant sheep

Daniel I. Edelstone, M.D., Mary E. Paulone, M.D., John J. Maljovec, M.D., and Margaret Hagberg, M.D.
Pittsburgh, Pennsylvania

We measured regional blood flows and cardiac output and calculated regional oxygen deliveries (blood flow × arterial blood oxygen concentration) and systemic oxygen delivery, oxygen extraction, and oxygen consumption as maternal hematocrit was varied randomly between 31% and 8% by exchange transfusion with plasma or packed sheep red blood cells. We observed three patterns of response: (1) In the heart, brain, and adrenal glands, oxygen delivery was constant or nearly constant over the range of hematocrits studied; (2) in the kidneys, splanchnic organs, and uteroplacental tissues, oxygen delivery was a linear function of hematocrit; (3) in the carcass tissues, oxygen delivery decreased slowly as hematocrits were reduced from 31% to 15% and dropped rapidly at hematocrits ≤15%. Systemic oxygen consumption was maintained at normal levels, despite reductions in hematocrit to about 15%, because oxygen extraction increased as compensation. At lower hematocrits, systemic oxygen consumption fell in association with a metabolic acidemia, suggesting that, with this severity of acute anemia, oxygen supply to some tissues in the pregnant sheep was inadequate for tissue metabolic demands. (Am J Obstet Gynecol 1987;156: 740-8.)

Key words: Acute isovolemic anemia, cardiac output distribution, maternal acid-base balance

At all developmental ages, anemia affects a wide variety of cardiovascular functions.[1-3] Two important functions affected are tissue blood flow and tissue oxygen delivery.[3,4] In nonpregnant animals, responses of individual organs and tissues to anemia vary between tissues, chiefly because of two factors: (1) Tissues regulate blood flow in direct response to changes in blood oxygen concentration or tissue oxygen availability; (2) anemia induces alterations in blood viscosity that directly influence blood flow.[3-5] Although alterations in viscosity (at any given shear rate) affect all organs and tissues equally, changes in vascular tone secondary to reductions in oxygen concentration or oxygen availability differ considerably among tissues. As such, the vascular effects of anemia show regional variations. Experiments done on fetal,[1] neonatal,[2] and nonpregnant adult animals[3] have shown that blood flows to the brain, heart, and adrenal glands increase sufficiently during anemia so that oxygen delivery (blood flow × arterial blood oxygen concentration) to these organs is maintained at normal or nearly normal levels. In contrast, in virtually all other organs, perfusion increases only modestly or not at all with anemia, and thus oxygen delivery falls as a function of decreasing hematocrit. Similar experiments have not been performed in pregnant animals. Such experiments would be of importance for at least two reasons. First, normal pregnancy is associated with considerable cardiovascular changes.[6] The ways in which maternal tissues respond to the further cardiovascular stresses of anemia may differ from those of the nonpregnant animal. Second, maternal anemia is a common complication of human pregnancy[7] and has been associated with increases in maternal morbidity and mortality rates. Data on the cardiovascular adjustments of pregnant animals to anemia may help to explain why morbidity and mortality rates are increased during pregnancy.

The purpose of our experiments was to identify the relationships of organ blood flows and oxygen deliv-

eries to maternal hematocrit during acutely induced anemia in pregnant animals. We also planned to measure cardiac output and systemic oxygen delivery and oxygen consumption during anemia to establish how the anemic state affects maternal oxidative metabolism. The fetal and placental responses to acute maternal anemia have previously been evaluated and are the subject of a separate report.[8]

Methods

Preparation of animals. We surgically prepared seven singleton pregnant sheep in which gestational age ranged from 105 to 125 days (term = 147 days). A spinal or epidural anesthetic (tetracaine hydrochloride, 1%) was administered to each sheep, after which catheters were inserted into two maternal hind limb arteries and one vein. Catheters were passed in a retrograde direction via a carotid artery into the left ventricle and via a jugular vein into the right ventricle. Catheter placements were verified by observation of the characteristic pressure wave forms produced by the left and right ventricles. Two to 4 days later, we studied the unanesthetized mothers as they stood quietly in an open transport cage. Five of the seven animals were studied on the fourth postoperative day, one on the third, and one on the second.

Experimental procedures. We measured cardiac output, systemic oxygen delivery and oxygen consumption, acid-base balance, and regional blood flows and oxygen deliveries at maternal hematocrits ranging from 31% to 8%. To vary the maternal hematocrit, we performed isovolemic exchange transfusions by infusing packed sheep red blood cells or plasma through one vascular catheter while withdrawing blood at the same rate from a second catheter.[1-3] Hematocrits were changed gradually over a period of 1 to 4 hours, during which time arterial blood pressure and heart rate were continuously monitored (Statham P23Db transducers) and recorded (Beckman R611A polygraph recorder).

As the exchange transfusions were progressing, we measured hematocrit periodically. When hematocrit had reached a value selected randomly, we stopped the exchange transfusion. After maternal hematocrit, heart rate, and arterial blood pressure were stable for at least 30 minutes, we withdrew 0.6 ml blood samples simultaneously from the arterial and right ventricular catheters. We analyzed these samples within 15 minutes for the following: P_{O_2}, P_{CO_2}, and pH with a blood gas analyzer (Instruments Laboratories), oxygen concentration with an oxygen content analyzer (Lex-O_2-Con), and hematocrit with a microhematocrit centrifuge.[1] Immediately after the blood sampling, we injected radionuclide-labeled microspheres (labeled with either iodine 125, cerium 141, chromium 51, strontium 85, niobium 95, or scandium 46, 15 μm in diameter) into the left ventricle while withdrawing an arterial blood reference sample at a rate of 7.9 ml/min.[9] We used this high withdrawal rate during the microsphere injections to ensure that blood flow measurements made in the anemic animals were accurate.[10] The volume of maternal blood drawn during each study was replaced with whole blood or plasma so that a constant intravascular blood volume could be maintained.

In preliminary experiments we determined that we needed to inject 2 to 5 × 10^6 microspheres to have sufficient numbers of particles in the organs and in the reference arterial blood samples from which precise calculations of organ blood flows could be made. There were no cumulative effects of multiple injections of microspheres (maximum total spheres injected = 20 × 10^6) on maternal arterial blood pressure or heart rate.[9] In all cases arterial blood pressure and heart rate were stable before, during, and after the microsphere injections. When the measurements were completed at any given maternal hematocrit, we increased or decreased the hematocrit to a new level and repeated the oxygen and flow measurements. An average of five such measurements (range three to six) was made in each of the seven sheep. The exact hematocrit at which measurements were made varied from one sheep to the next. No attempt was made to study all animals at the same hematocrit levels.

Preparation of tissues and calculation and analysis of data. At the completion of the experiment, sheep were killed with an overdose of sodium pentobarbital, and catheter locations were verified visually. All organs were dissected, weighed, and processed further with standard techniques.[9] Organs were incinerated individually at 280° C for 48 hours, after which the ashed tissues were packed into counting vials. The amounts of each radionuclide in the organs and arterial blood reference samples were measured with a well-type gamma scintillation counter (Model 1185R, Tracor) and a 1024-channel pulse-height analyzer (Ultima II, Norland). Nuclide isotope separation was performed by computer, which used a least-squares fitting analysis to distinguish the various isotopes contained in each sample (Nova 3, Data General; average error in the calculation of corrected radioactive counts per minute for each isotope was <5%). Arterial blood reference samples and all organs, except the adrenal glands, contained >1500 microspheres to ensure that the error in any blood flow measurement was <5% at the 95% confidence limits.[9] For the adrenal glands all tissues contained >400 microspheres (maximum error 10%, 95% confidence limits).

We computed the organ blood flows and oxygen deliveries as follows[1-3]:

$$\text{Organ blood flow} = (CPM_{organ}/CPM_{ref}) \cdot \dot{Q}_{ref}$$
$$\text{Organ oxygen delivery} = (\text{organ blood flow}) \cdot CaO_2$$

where CPM_{organ} = radioactive counts per minute in the

organ, CPM_{ref} = radioactive counts per minute in the arterial blood reference sample, $\dot{Q}ref$ = arterial reference blood flow, determined by calibration of the withdrawal pump, and CaO_2 = arterial blood oxygen concentration.

Cardiac output was calculated as follows[3,6]:

$$\text{Cardiac output} = (CPM_{total}/CPM_{ref}) \cdot \dot{Q}_{ref}$$

where CPM_{total} = total radioactive counts per minute injected into the left ventricle. To determine the total counts per minute injected, we used an aliquot system.[3] This method has been shown in other laboratories[3,6] to provide accurate measurements of cardiac output when proper precautions for counting high rates are taken. To be certain of its validity in our own laboratory, we calculated cardiac output as above and also as follows in two of the animals. In these two sheep all tissues were counted for radioactivity. Cardiac output was then equal to the sum of the blood flows to all of the individual organs plus the carcass tissues (skeletal muscle, skin, skeleton, and adipose tissue). Cardiac output calculated by the two methods differed by an average of 11% (±3% SD; n = 10 measurements made in two sheep). In the remaining five animals in which flow and oxygen delivery to carcass tissues were not measured directly, these variables were calculated as follows:

$$\text{Carcass blood flow} = \text{cardiac output} - \text{sum of all organ blood flows}$$

$$\text{Carcass oxygen delivery} = (\text{carcass blood flow}) \cdot CaO_2$$

Three variables of systemic oxygenation were computed with modifications of the Fick principle[5]:

$$\text{Systemic oxygen delivery} = (\text{cardiac output}) \cdot CaO_2$$

$$\text{Systemic oxygen consumption} = (\text{cardiac output}) \cdot (CaO_2 - C\bar{v}O_2)$$

$$\text{Systemic oxygen extraction} = (CaO_2 - C\bar{v}O_2)/CaO_2$$

where $C\bar{v}O_2$ = oxygen concentration in right ventricular blood.

There were no obvious diferences in basal maternal blood pressures, heart rates, or hematocrits as functions of gestational age (over the range studied, 109 to 127 days) or length of postoperative recovery period (2, 3, or 4 days). Therefore we based our analyses on the pooled data (32 measurements obtained in seven sheep). Two analyses were performed. First, organ blood flows and oxygen deliveries, maternal cardiac output, and systemic oxygen delivery, oxygen extraction, and oxygen consumption (dependent variables) were plotted against maternal hematocrit (independent variable). We analyzed the data by means of a weighted least-squares method based on covariance analysis that allowed us to generate regression lines that took into account responses seen in individual animals.[11] Linear, logarithmic, and power functions were all tested for best fit; the function selected as best describing each relationship had the greatest correlation coefficient associated with the least residual sum of squares. Second, we arbitrarily divided up the data into five equal hematocrit ranges so that we could present all of our data in tabular form. These data were analyzed with a one-way analysis of variance.[11] When significant differences were observed, we used the Newman-Keuls test (with Kramer's modification for comparisons involving unequal n) to identify which dependent variables differed from the rest.[11] In all statistical analyses, p values <0.05 were used to indicate statistically significant correlations.

Results

In the seven pregnant sheep studied, gestational age was 115 ± 7 days (mean ± SD) on the day of study, body weight was 42 ± 6 kg, and hematocrit was

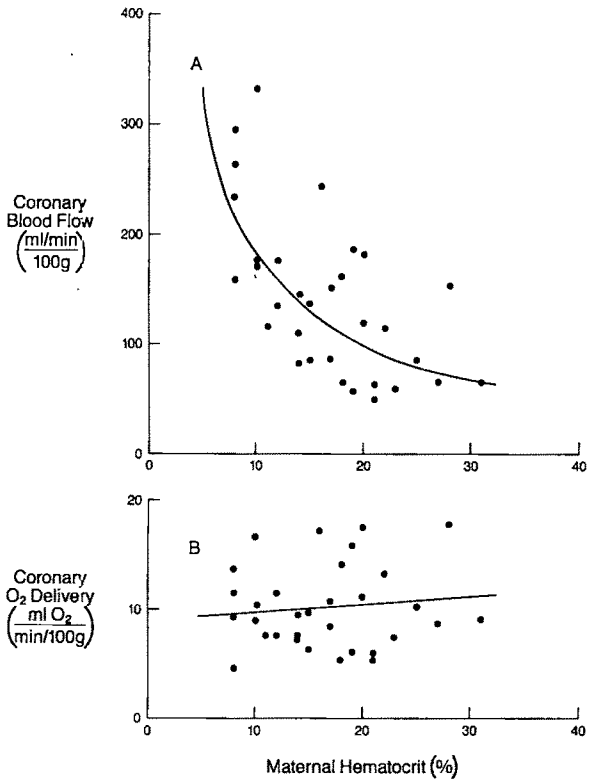

Fig. 1. Example of first pattern of response to acute maternal anemia. 27% ± 2%. In response to reductions in maternal hematocrit, heart rate increased linearly, mean arterial blood pressure did not change significantly, arterial blood oxygen concentration fell linearly, and a combination of metabolic acidosis (decreased base excess) and respiratory alkalosis (decreased P_{CO_2}) developed (Table I).

Blood flow and oxygen delivery to maternal organs and tissues during acute isovolemic anemia could be classified into three general patterns of response. Figs. 1 to 3 illustrate the data obtained on three specific tissues, heart, kidneys, and carcass, that serve as examples of the three responses observed. Tables II and III present the data for all the organ and tissue responses, expressed in units of absolute flow and oxygen delivery (Table II) or as percentages of cardiac output (Table III).

In the first pattern, typified by the heart, brain, and adrenal glands, blood flow (absolute flow in Table II and flow as a percentage of total cardiac output in Table III) increased as maternal hematocrit decreased. In the case of the heart (Fig. 1, Table II), oxygen delivery was constant over the range of hematocrits studied. In the brain and adrenal glands, however, oxygen delivery decreased as maternal hematocrit was reduced (Table II). In the second pattern of response, organ blood flows did not change significantly in response to acute maternal anemia (Tables II and III). Because of these blood flow responses, organ oxygen deliveries decreased linearly as hematocrit was reduced. Organs exhibiting this second response pattern included the kidneys, stomach, intestine, colon, spleen, liver, and uteroplacenta. Fig. 2 illustrates the data for the renal response to acute maternal anemia as an example of this response pattern. The third pattern of response was observed in carcass tissues (skeletal muscles, skeleton, skin, and adipose tissues). Fig. 3 and Table II show that blood flow to carcass tissues increased as hematocrit was reduced to 15%, then decreased at lower hematocrit levels. Oxygen delivery did not change significantly as hematocrit was decreased from 31% to about 15% but fell rapidly when hematocrit was lowered below about 15%.

Because of the flow responses to acute maternal anemia observed in the various maternal organs and tissues, cardiac output increased as hematocrit was de-
